If a solid in suspension is a conductor, such as manganese dioxide or carbon, it will cause sprouting of the cathode metal. The electrolyte should be clarified before going to the cells and all foreign matter should be kept out of the electrolyte. When the cells become foul with manganese dioxide, so that it is in suspension, sprouting is more prevalent than at other times. The sprouting is always more intense on the bottom of the cathodes, where there is a higher concentration of the suspended particles.

It has long been the practice in electrolytic copper refining to add moderate amounts of glue at regular intervals. At the suggestion of Willis T. Burns, glue was tried and found to be beneficial. Too much glue causes brittle metal, starts re-solution of the zinc deposit, and may prevent the deposition of any zinc ; the addition of moderate amounts will greatly retard sprouting and give better current efficiency, especially when small amounts of ar enic and antimony are present. After the add t on of glue there is a slight voltage rise and the gas bubbles from the cathode deposit greatly increase in size, probably due to a change in the character of the surface film of the electrolyte. Glue appears to make this film tougher so that the bubbles of gas hang on to the sprouts and raised spots for a longer period, partly insulating them. The low places in the deposit appear to build up faster, giving a much denser deposit with glue than without it. The effect of the glue on the electrolyte only lasts for a short period. Evidently the glue is decomposed, because during periods of re-solution when an excessive amount of gas is coming off it must be added more often. With pure electrolyte, the addition of the glue is not necessary. But the effort should be made to purify the electrolyte, instead of doping it. Sugar, wood juice, starch, and a number of other agents give approximately the same results, but glue is the most trustworthy and cheapest.

Casting Practice.—The zinc-casting plant contains two coal-fired reverberatories with a capacity of from 100 to 125 tons per furnace and one electric furnace with a daily rated capacity of 200 tons. After a six-months' trial the use of the electric furnace was discontinued for the following reasons : (1) When melting zinc cathodes, the dross formed coats over the surface of the metal, preventing the transfer of heat to the bath. (2) It is impossible to get nearly the full production without volatilizing considerable metal ; with a production of 170 tons per day, over 3½% of the zinc charged is volatilized. (3) The metal bath cools during charging so that heat is required in the muffles to keep the metal hot enough for casting. (4) At 70 tons capacity the furnace compares very favourably with the coal-fired furnaces, but when the investment is considered the furnace is a failure for zinc-cathode melting. (5) The heat in the resistor troughs is so intense, when melting 100 tons per day, that the trough construction will not stand up, causing frequent long delays for repairs. The work of this furnace confirmed the laboratory experiments, that when zinc cathodes are melted they will produce a definite amount of dross. To get a good melting recovery the dross must be worked to separate the metal from the oxide.

Zinc cathode sheets are apt to be porous to a certain extent and one side is covered with sprouts or raised spots. There is also a coating of zinc sulphate. Even when melted in a covered crucible, from 4 to 5% of dross is formed. This dross contains metallics and may be reduced 40 or 50% in weight if worked hot with ammonium chloride. The best recovery of the metal over a month's

operation was 96[illegible]; 3[illegible]% of the metal went to form dross, which [illegible] saved 8[illegible]% zinc.

The zinc melting reverberatories are made of common brick below the metal line and of firebrick above. To avoid metal leakage the whole furnace is set on a sheet metal pan, which is supported by I beams set on concrete piers. This construction permits air cooling at the bottom. The main chamber of the reverberatories is built rather high so that there is a deep bath of metal and a big stack of cathodes at all times; this gives a large surface of metal exposed to the heat. The melting zinc running down the surface of the stack carries away the dross and always presents a new surface of bright metal to the hot gases from the firebox, which is large and deep. It is operated as a partial gas producer so that the resulting gases will be reducing, to avoid oxidation of the metal. The dross from the melting cathodes is carried down with the molten zinc and floats on the top of the bath, gradually slowing up the furnace. At intervals this dross is rabbled with ammonium chloride, which causes the particles of molten zinc to combine and sink into the bath. Once every 24 hours the dry dross is completely removed from the furnace and further worked, while hot, in a revolving cement mixer, to which oil and ammonium chloride are added. The addition of a small amount of oil and sawdust to the dross helps to keep up the temperature. Approximately 50% of the zinc contained in the furnace dross is recovered as metal in this way. This metal collects in the bottom of the cement mixer and is tapped out through a hole into moulds.

The loaded cathode cars are brought to the charging stand over which there is a one-ton electric hoist, which places 4 or 5 tons of the cathodes upon a roller coaster. This conveys the metal to the charging doors in the top of the furnace; when the charging door is swung open and the brake on the roller coaster released the bundle of cathodes slides into the furnace. It is only necessary for the furnace to be open a few seconds while charging. Every precaution is taken to exclude the air from the furnace while melting; all openings are sealed except during the dross-skimming period. The furnace is allowed to cool down about 150° C. before opening it to skim the dross.

The molten metal is dipped from metal sealed dipping muffles and poured into 50 lb. slab moulds of which there are 40 in line with each muffle. The dipping ladles hold over 200 lb. of molten zinc and are carried from an overhead crawl. Each is operated by one ladleman who has a helper to mark and stack back the slabs from the moulds. A sample of metal is taken from every twentieth ladle and cast in pencils in a split graphite mould; these pencils are broken up and combined to form the sample representing each day's production.

Zinc-Dust Plant.—Approximately 8% of the zinc produced in the tank room is required to precipitate copper and cadmium. The zinc atomizing plant is made in two units, and either may be shut down without interfering with the other. Each unit consists of an oil-fired Rockwell furnace, two blowing nozzles, and a settling chamber, with a superimposed bag house. The Rockwell furnace receives the molten zinc from the melting furnace by means of an electric hoist ladle and crawl system. The carbon crucible of the Rockwell furnace is provided with two carbon rods in the bottom, tapped with $\frac{1}{8}$ in. holes through which the molten zinc flows to the atomizing nozzles. Air from the nozzles strikes the hot zinc at right angles and blows it into the settling chamber. This chamber has bags above through which the air is filtered, leaving the dust to drop back into the hoppers which are provided in the bottom of the chamber to draw the dust into cars. There are three factors to be considered: (1) The metal must be hot; (2) the air pressure should be at least 85 lb. at the nozzle; (3) the stream of metal should be small, not over $\frac{3}{16}$ in. in diameter. If the air pressure at the nozzle is 300 lb. less attention must be paid to the other two factors.

The authors also give an account of the treatment of residues for the extraction of copper and lead, and they discuss in detail a great many theoretical and practical points connected with the various stages of the process and plant.

SHORT NOTICES

Open-cut Mining.—In the *Mining and Scientific Press* for April 16, A. B. Parsons describes open-cut mining by steam-shovel as practised at the Nevada Consolidated's copper mines.

Winding Engine at Quincy.—The *Engineer* for May 20 describes a large new winding engine at the Quincy copper mine, Lake Superior. It is a 4-cylinder, cross-compound condensing engine, with a 30 ft. drum, and is capable of raising ten-ton loads with a rope speed of 3,200 ft. per minute from depths of 6,600 ft. to 8,600 ft. on the incline.

Mining at Fresnillo.—In the *Engineering and Mining Journal for* May 7, D. B. McAllister describes the new mining methods at the Fresnillo silver mines, Mexico.

Rehabilitation of French Mines.—*Engineering* for May 20 commences an article on the rehabilitation of French coal mines destroyed by the Germans during the war.

Concrete Shafts.—In the *Engineering and Mining Journal* for April 23, J. H. Stovel describes the concreting of two vertical shafts in iron minse in Alabama.

Concrete Shaft-Lining.—In the *Mining and Scientific Press* for April 30, A. B. Parsons describes the concrete shaft of the Chief Consolidated Mining Co., at Eureka, Utah.

Drill-steel.—The American Institute of Mining and Metallurgical Engineers has published a paper by B. Tillson on the breakage and heat treatment of rock-drill steel.

Stope Survey.—In a paper presented at the May meeting of the Institution of Mining and Metallurgy, F. P. Caddy described the method of stope measuring at the Passagem mine, Brazil.

Surveying Instruments.—The *Camborne School of Mines Magazine* for May contains a paper by W. H. Connell, of T. Cooke & Sons, Ltd., on the renaissance of British instrument making.

Electrical Prospecting.—The *Engineering and Mining Journal* for May 7 and 14 contains an abbreviated translation of a paper by C. Schlumberger on underground prospecting by electric current.

Valuation of Mineral Properties.—The *Iron and Coal Trades Review* for May 13 quotes from a paper by T. A. O'Donahue on the valuation of mineral properties, with special reference to post-war conditions.

Cleaning Blast-Furnace Gas.—A paper was read by S. H. Fowles at the May meeting of the Iron and Steel Institute on the cleaning of blast-furnace gas, dealing particularly with the Halberg-Beth plant.

Electrostatic Precipitation.—The *Mining and Scientific Press* for April 9 contains a description of the Cottrell electrostatic fume-precipitation process. Attached to it is a useful bibliography on the subject.

Electrolytic Zinc.—In *Chemical and Metallurgical Engineering* for April 20, H. R. Hanley writes on the removal of arsenic from zinc electrolyte by means of sulphuretted hydrogen.

Copper in Molybdenum Ores.—In *Chemical and Metallurgical Engineering* for May 11, J. P. Bonardi and M. Shapiro describe methods for removing all copper from molybdenum ores before smelting for ferro-molybdenum, and also point out precautions necessary in the analysis for copper in the presence of molybdenum.

Nickel Alloys.—In *Chemical and Metallurgical Engineering* for April 13, P. D. Merica describes a great number of nickel alloys used where resistance to acid and high-temperature steam is desired, and also alloys for electrical purposes.

Aluminium in Engineering.—In the *Engineer* for May 6, J. G. A. Rhodin commences a series of articles on aluminium and its alloys in engineering.

Tin in New Mexico.—In the *Mining and Scientific Press* for April 23, F. S. Naething describes the Black Range tin district, New Mexico.

Quicksilver in Spain.—In the *Mining and Scientific Press* for April 23, H. W. Gould describes the quicksilver mining and metallurgy at Almaden, Spain.

The Earth's Crust.—The *Geographical Journal* for May contains the report of a lecture by Colonel E. A. Tandy, giving some novel views following the theory of isostasy.

Mackenzie River Oilfields.—The *Canadian Mining Journal* for May 6 contains a paper by E. M Kindle containing general suggestions to oil prospectors in the Mackenzie River oilfields.

Origin of Petroleum.—At the meeting of the Institution of Petroleum Technologists held on May 10, P. Carmody read a paper recommending that a special study as to the origin of petroleum should be made at Trinidad, where a greater variety of oils, gas, bitumen, and pitch are found than anywhere else in the world.

Alsatian Potash.—In *Chemical and Metallurgical Engineering*, H. Vigneron describes the Alsatian potash industry.

Californian Potash.—In *Chemical and Metallurgical Engineering* for April 20, L. W. Chapman describes the refining plants at Owens and Searles Lakes, used in separating carbonate of soda, common salt, sodium borate, and potassium chloride from the natural deposits.

Borate Deposits.—In *Economic Geology* for May, N. F. Foshag discusses the origin of colemanite, the borate of lime, found in California.

Vanadiferous Asphaltites.—In the *Engineering and Mining Journal* for May 7, J. G. Baragwanath describes the asphaltites occurring in Peru; these contain vanadium, but not in sufficient quantities to make extraction profitable.

Salt Deposits in Nigeria.— The *Bulletin* of the Imperial Institute, No. 4, 1920, just published, contains a report on samples of sodium, potassium, and magnesium salts found in Nigeria.

Trevithick in Peru.—In the *Engineering and Mining Journal* for April 16, W. B. Paley gives an account of the steam engines built by Trevithick at Cerro de Pasco and elsewhere in Peru.

Alignment Charts.—In a paper presented at the May meeting of the Institution of Mining and Metallurgy, J. A. P. Gibb drew attention to the advantages of alignment charts over intercept and correlation charts and gave a number of applications of this system of calculation.

Scottish Water-power. –*Engineering* for May 20 contains further details of the new hydro-electric power scheme of the British Aluminium Company.

RECENT PATENTS PUBLISHED

A copy of the specification of any of the patents mentioned in this column can be obtained by sending 1s. to the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. 2, with a note of the number and year of the patent.

9,155 of 1919 (140,039). Société Belge d'Outillage Pneumatique (Ateliers Rorive), Brussels. Improved construction of hand hammer-drills.

31,791 of 1919 (162,026). F. E. Elmore, London. In the treatment of argentiferous zinc-lead sulphides, mixing with an excess of common salt or other chloride and heating to a temperature of 450° to 500° C. At this temperature the silver and lead are chloridized but not volatilized, while the zinc sulphide is unaltered.

31,936 of 1919 (162,030). S. Field and Metals Extraction Corporation, London. In removing impurities from zinc sulphate solutions before electrolysing the addition of mercuric sulphate and zinc dust or aluminium or an aluminium-zinc alloy.

32,539 of 1919 (137,288). J. A. Thibault, Paris. Method of producing litharge and red lead from metallic lead.

821 of 1920 (161,654). P. A. Mackay, London. For recovering tin from scrap tinplate by dipping the scrap in oleum, that is, sulphuric acid containing free SO_3.

822 of 1920 (161,655). P. A. Mackay, London. For the purpose of making strontium and barium sulphates opaque, placing them after fine grinding in oleum, or strong sulphuric acid.

823 of 1920 (161,656). P. A. Mackay, London. Method of obtaining copper sulphate direct from metallic copper.

1,231 of 1920 (161,310). H. G. Wildman, Westmount, Quebec. Making alumina from common clay by boiling it in an alkaline solution, then treating with sulphurous acid, which makes aluminium sulphite, the latter being readily split into alumina and sulphurous acid.

1,240 of 1920 (162,038). C. Ellis, New York. Method of producing finely divided metals or suboxides.

2,245 of 1920 (162,082). C. M. Conder and G. T. Vivian, Camborne. A stamp-mill in which the tappet head and shoe are mounted to a beam at right angles, the other end of which is pivoted, the raising cam actuating the beam at the end near the tappet head.

3,640 of 1920 (161,761). G. H. T. Rayner and P. Rayner, Sheffield. Improvements in the valve arrangement of the inventors' patent 138,304.

3,692 of 1920 (161,375). E. C. Vigeon and J. McConway, Hebburn-on-Tyne. An apparatus for evenly moistening roasted ore before being sent to leaching tanks, the object being to avoid dust and the formation of lumps.

NEW BOOKS, PAMPHLETS, Etc.

[illegible] *The Mining Magazine* [illegible]

The Oil and Petroleum Manual, 1921. By WALTER R. SKINNER. Cloth, octavo, 320 pages. Price 7s. 6d. net. London: Walter R. Skinner, 11 and 12 Clements Lane, E.C.4. This is the twelfth yearly issue of a well known publication which gives particulars of all the oil and petroleum companies known in England.

The Petroleum Year Book, 1921. By SYDNEY H. NORTH. Cloth, octavo, 280 pages. Price 10s. 6d. net. London: The St. James's Press.

Copper Refining. By LAWRENCE ADDICKS. Cloth, octavo, 220 pages. Price 17s. net. New York and London: McGraw-Hill Book Company.

Technical Methods of Analysis, as employed in the laboratories of Arthur D. Little, Inc. By R. C. GRIFFIN. Cloth, octavo, 670 pages. Price 33s. net. New York and London: McGraw-Hill Book Company.

Metallic Alloys: their Structure and Constitution. By Dr. G. H. GULLIVER. Fourth edition. Cloth, octavo, 440 pages, illustrated. Price 15s. net. London: Charles Griffin & Co., Ltd.

Problems in Land and Mine Surveying. By DANIEL DAVIES. Second edition. Cloth, octavo, 350 pages, illustrated. Price 12s. 6d. net. London: Charles Griffin & Co., Ltd.

Text-book of Practical Hydraulics. By JAMES PARK. Second edition. Cloth, octavo, 310 pages, illustrated. Price, 21s. net. London: Charles Griffin & Co., Ltd.

Compressed-air Plant. By ROBERT PEELE. Fourth edition. Cloth, octavo, 500 pages, illustrated. Price 25s. net. New York: John Wiley & Sons; London: Chapman & Hall, Ltd.

Pumping by Compressed Air. By EDMUND M. IVENS. Second edition. Cloth, octavo, 270 pages illustrated. Price 22s. net. New York: John Wiley & Sons; London: Chapman & Hall, Ltd.

Salt and Gypsum Resources of South Australia. By R. LOCKHART JACK. Bulletin No. 8 of the Geological Survey of South Africa.

COMPANY REPORTS

Waihi Gold.—This company has been operating a gold mine in New Zealand since 1887. Regular production began in 1892, and the first dividend was paid for the year 1893. The output and profits gradually increased, and were on a large scale from 1901 to 1910. Afterwards the operations contracted owing to the impoverishment of the ore in depth. The report for the year 1920 shows that 159,308 tons of ore was raised, of which 42,066 tons came from the Martha lode, 34,241 tons from the Royal, 19,839 tons from the Edward, 14,599 tons from the Empire, and the remainder from sixteen other places. The average assay of the ore was 6·6 dwt. gold and 2¾ oz. silver per ton. The yield of bullion, taking gold at 84s. per oz. and silver at 2s. per oz., was estimated to be worth £242,264. The actual amount received was £341,432. The working profit was £146,811, out of which £99,181 was distributed as dividend, being at the rate of 20% tax paid, while £47,629 was paid as income tax and £14,907 was written off for depreciation. The ore reserve is estimated at 778,565 tons, averaging 33s. 9d. per ton with gold at par and silver at 2s. per oz.; of this amount 254,737 tons is not immediately available for extraction. Development disclosed 116,521 tons of ore during the year. Additional electric pumping plant has arrived at the mine, so that it is now possible to sink deeper. A thirteenth level is being opened from No. 4 shaft. Since the beginning of operations the income from the sale of gold has been £12,987,603, out of which £5,172,808 has been distributed as dividends, tax paid.

Golden Horse-Shoe Estates.—This company was formed in 1899 to acquire property at Kalgoorlie, West Australia. Very large profits were made from 1900 to 1909, but since then the output and dividends have been much lower. The report for 1920 shows that 125,340 long tons of ore yielded 54,574 oz. of gold, which realized £324,460, of which £87,223 represented premium. The net profit was £65,489, while £75,000 was distributed as dividend, being at the rate of 5%. The development was restricted owing to labour shortage, as was the case the year before. J. W. Sutherland, the manager, estimates the reserve at 637,330 tons, averaging 8·75 dwt. per ton, as compared with 678,296 tons averaging 9 dwt. the year before. The working cost was 37s. per ton, as compared with 32s 6d. in 1919 and 22s. in 1914. The total output of ore since the beginning has been 4,253,635 tons, and the total yield of gold 2,688,840 oz., while £3,517,500 has been distributed in dividends.

Balaghat Gold Mines.—This company operates a gold mine in the Kolar district, Mysore State, South India, belonging to the John Taylor & Sons group. It has not been so important a producer as the other members of the group, Mysore, Champion Reef, Nundydroog, and Ooregum. Eighteen months ago it was reconstructed so as to provide additional funds for a resumption of development. The report now issued covers the fourteen months ended December 31 last. During this period 45,050 tons of ore was milled, yielding 25,833 oz. of gold, and 76,250 tons of tailing was cyanided, yielding 6,629 oz., making a total yield of 32,462 oz., which sold for £163,715. The working cost was £123,454, and after the payment of royalty the profit was £33,296, out of which £23,318 has been distributed as dividend, being 2s. 4½d. on the 10% preference shares, and 1s. 1½d. on the ordinary shares, both of 10s. each. During the year driving on the rich ore-shoot on the 2,600 ft. level was continued, and its total length was found to be 842 ft., averaging 33½ dwt. per ton over a width of 40 in. At the deeper levels nothing further was discovered, though the drive on the 4,000 ft. level is giving promising results. The reserve was estimated on December 31 at 91,755 tons, an increase of 16,725 tons during the year. There is also 177,000 tons of accumulated tailing awaiting treatment. A new sand plant, with a capacity of 4,000 tons per month, is in course of erection. This will replace the old plant, which is now out of date. The slime plant is being duplicated; on completion its capacity will be 250 tons per day.

Rhodesia Gold Mining and Investment.—This company belongs to the Lewis & Marks group and was formed in 1910 to develop and finance gold-mining properties in Rhodesia. It has large holdings in Lonely Reef and Cam & Motor, works the Huntsman mine, and lets the Bernheim on tribute. It also controlled the Sabi company, but owing to the failure of the property the company

went into liquidation last year. The report for the year 1920 shows that at the Huntsman mine 7,279 tons of ore, averaging 13·8 dwt. per ton, was treated for a yield of 4,043 oz. of gold, the net profit realized being £1,029. The mine continues to develop well on a small scale. At the Bernheim mine the tributers treated 4,991 tons for a yield of 2,539 oz., and the royalty accruing to the company was £1,784. Owing to an accident to the plant the tributers have recently been obliged to cease work, but the company is granting them financial assistance, and work will be resumed shortly. For the five months January to May, 1920, during which the Sabi was in operation 5,700 tons of ore yielded 1,067 oz. The accounts for the year show receipts £19,981 from dividends, chiefly Lonely Reef. Owing to the failure of the Sabi Company a loss on investments of £148,709 was incurred, and the adverse balance for the year was £130,529. There have been other small losses on unsuccessful properties, so it has been decided to reduce the capital of the company from £300,000 to £150,000 by cancelling 10s. of each £1 share.

Rezende Mines.—This company operates gold mines in Rhodesia, and has had a long history of varying fortunes, as recorded already in these columns. Sir Abe Bailey secured control a few years ago, and undertook an active development campaign. Satisfactory dividends have been paid for the years 1918 to 1920. The report for 1920 shows that 66,500 tons of ore was treated for a yield of 29,506 oz. of gold. The income, including premium on gold, was £164,604, and the cost, including taxes and depreciation, was £122,908. The profit was £41,696, and the dividends amounted to £48,000, being at the rate of 40%. The ore reserve is estimated at 140,268 tons, averaging 10 dwt. per ton. All of this is in the eastern section, the central section having been exhausted. The development work on the new seventh level in the eastern section appears to be giving fairly good results.

West Rand Consolidated Mines.—This company belongs to the Albu group, and was formed in 1903 to acquire a number of gold-mining properties in the far west Rand. Other adjoining properties have been acquired since. There are two workings on the Main Reef, and three on the Battery Reef farther south. The operations have not been profitable on the whole, the only dividend having been one of 3¾% paid for 1909. The share capital is £2,004,424, and there are £325,000 debentures. The report for 1920 shows that 396,268 tons of ore was raised, of which 232,688 tons came from the Main Reef and 163,580 tons from the Battery Reef. After sorting, 378,100 tons, averaging 6·27 dwt. per ton, was sent to the mill. The yield of gold by amalgamation was 64,297 oz., and by cyanide 40,878 oz., making a total of 105,175 oz. The revenue from the sale of gold was £572,847, of which about £125,000 represented premium. The working cost was £518,170, leaving a working profit of £54,676, of which £19,749 was paid as debenture interest. The revenue per ton of ore milled was 30s. 3d., and the cost per ton 27s. 5d. The ore reserve is estimated at 1,205,199 tons, averaging 6·5 dwt. per ton. It will be seen that the continuance of working depends on the relative movements of gold premium and costs. A new central pumping plant is being installed, and it will be possible soon to recommence shaft-sinking on the Main Reef.

Roodepoort United Main Reef.—This company belongs to the Albu group, and was formed in 1887 to work gold-mining property in the middle west Rand. Roodepoort Deep was absorbed in 1898, and Roodepoort Gold in 1909. Dividends were paid from 1894 to 1910, but none since. There is at present an accumulated loan of £365,782 owing to the parent company, the General Mining and Finance Corporation. Operations during 1920 could only be continued by adopting a policy of selective mining, and stopping development and shaft-sinking. The report for 1920 shows that 275,016 tons of ore was mined, and 274,200 tons, averaging 4·5 dwt. per ton, was sent to the mill. The yield of gold by amalgamation was 43,030 oz., and by cyanide 14,861 oz., making a total of 57,891 oz. The revenue from the sale of gold was £315,863, of which about £69,000 represented premium. The working cost was £311,770, leaving a working profit of £4,092. The revenue per ton of ore milled was 23s., and the cost per ton 22s. 9d. The reserve is estimated at 249,108 tons, averaging 5·8 dwt. over a width of 41 in. The present position at the mine is critical.

Aurora West United.—This company belongs to the Albu group, and was formed in 1891 to work gold-mining property in the middle west Rand. The property of the Aurora company was absorbed in 1897. The mine was never a financial success, and during the last year or two has only been kept going by means of a policy of selective mining. The report for 1920 shows that 146,192 tons of ore was raised, and after the removal of 10% waste, 131,840 tons, averaging 5·63 dwt. per ton, was sent to the mill. The yield of gold by amalgamation was 22,819 oz., and by cyanide 11,120 oz., making a total of 33,939 oz. The revenue from the sale of gold was £184,770, of which about £38,000 represented premium. The working cost was £181,184, leaving a working profit of £3,586. The revenue per ton milled was 28s., and the working cost 27s. 6d. The reserve of payable ore was estimated on December 31 at 32,050 tons, averaging 7·3 dwt. over 42 in., but if gold rose to 110s. per oz., a further 80 570 tons could be worked. The outlook for the mine at the present time is serious.

New Unified Main Reef. — This company belongs to the Barnato group, and was formed in 1891 to take over the properties of the Eagle and National gold-mining companies operating in the western part of the Rand. Other properties adjoining have since been acquired. Dividends have been paid since 1908. The report for 1920 shows that 128,500 tons of ore, averaging 5·32 dwt. gold per ton, was raised and sent to the mill. The yield of gold by amalgamation was 20,720 oz., and by cyanide 11,960 oz., making a total of 32,680 oz. The revenue from the sale of gold was £182,766, of which about £43,000 represented premium. The working cost was £141,729, leaving a working profit of £41,036. The revenue per ton milled was 28s 6d., the working cost 22s. 1d., and the working profit 6s. 5d. The shareholders received £37,500, the dividends (Nos. 24 and 25) being at the rate of 5% and 10% respectively. The ore reserve at December 31 was calculated at 83,000 tons, averaging 6·2 dwt. over 46 in. There is also some reclamation ore of uncertain quantity to be mined. It is difficult to say how much longer the mine can be operated without loss.

New Goch.—This company belongs to the Albu group, and was formed, as the George Goch,

in 1887 to work gold mining property in the central Rand. Subsequently other adjoining properties were absorbed. Profits have not been great, and the dividends have totalled only 65%, being distributed for the years 1909 to 1911, and 1915 to 1917. During the past year or two the low assays of the ore, combined with the increasing costs, have made the continuance of operations difficult, and if it had not been for the gold premium the mine would have been closed. The report for 1920 shows that 191,030 tons of ore was raised, and after the removal of waste, 184,450 tons, averaging 4·86 dwt. per ton was sent to the mill. The yield of gold by amalgamation was 25,934 oz., and by cyanide 11,116 oz., making a total of 38,050 oz. In addition 2,704 oz. was recovered from accumulated slime. The revenue from the sale of gold was £222,626, of which about £49,000 accrued from premium. The working cost was £220,208. The revenue per ton was 24s. 2d., and the cost per ton 23s. 10d. The ore reserve at December 31 was calculated at 48,717 tons, averaging 6·9 dwt. over 46 in. If gold sold at 110s. per oz., an additional 56,915 tons, averaging 5 dwt. over 50 in., might be treated. There exists in the mine also much ore in pillars, and in Main Reef in the Leader stopes, but the amount and value of this cannot be estimated.

New Primrose.—This company belongs to the Barnato group, and was formed in 1887 to acquire claims on the outcrop six miles east of Johannesburg. Excellent dividends were paid until the approaching exhaustion of the mine three or four years ago. Since then part of the adjoining May mine was acquired, and, later, part of Glencairn was acquired, in both cases the properties being the remnants left by companies in liquidation. The report for 1920 shows that 225,874 tons of ore was raised, and 232,100 tons, averaging 4·44 dwt. per ton, was sent to the mill. The yield of gold by amalgamation was 32,101 oz., and by cyanide 15,383 oz., making a total of 47,484 oz. The revenue from the sale of gold was £268,104, of which about £66,000 represented premium. The working cost was £236,388, leaving a working profit of £31,715. The revenue per ton was 23s. 1d., the working cost 20s. 4d., and the working profit 2s. 9d. The shareholders received £16,250, the dividend (No. 51) being at the rate of 5%. The actual proved ore reserve in the Primrose is very small, being estimated on December 31 at 26,500 tons, averaging 7·6 dwt. over 54 in. Much ore remains, however, in various parts of the mine, and also in the May and Glencairn, and it is possible that operations will continue for another year or two, provided economic conditions allow.

Dundee Coal. — This company has operated coal deposits in the northern part of Natal for nearly thirty years. The report for 1920 shows that the output of the Burnside collieries was 212,795 tons, and of the St. George's colliery 104,480 tons, making a total of 317,275 tons, an increase of 14,599 tons as compared with the previous year. The receipts from the sale of coal and coke were £590,885, and the net profit was £33,835, out of which £33,577 was distributed in dividends (Nos. 40 and 41). The company has some excellent export contracts.

Glencoe (Natal) Collieries. — This company has worked coal deposits in the Dundee district, Natal, since 1902. Two years ago there was a setback owing to floods and influenza epidemic. The report for 1920 shows that a recovery has been made in output, and that profits are once more being earned. But for the shortage of railway trucks the output would have increased further. The amount of coal produced was 104,031 tons, as compared with 96,514 tons in 1919, and 186,800 tons in 1916. The amounts show a net profit of £17,153, out of which £5,354 was written off for depreciation, and £9,375 paid as dividend (No. 19), being at the rate of 3¾%. The manager remarks that the quality of native labour now obtainable is very poor.

New Brunswick Gas and Oilfields.—This company operates gas and oil lands in New Brunswick, Canada. The report for the year 1920 shows that the profit from the sale of gas was £26,101, and from oil £4,886. Other items brought the net income to £39,540. After allowance for taxes and depreciation, the net profit was £7,779. The dividends were at the rate of 6% on the preference shares, and 10% on the ordinary shares, less income tax in both cases. During the year a new oil well, No. 54, was drilled in the Stony Creek field to a depth of 2,745 ft., and it is now the most productive well. No. 53 was started, but owing to the hard rock encountered, drilling was suspended for a time. It is hoped to resume some time during the current year. Three of the producing gas-wells were deepened, and thereby additional flows of gas were obtained. The properties are on offer to the D'Arcy Exploration Co., acting on behalf of the Anglo-Persian Oil Co. During 1920 the D'Arcy Company had three drilling crews at work, and further drilling is to be done during 1921.

Apex (Trinidad) Oilfields.—This company was formed in 1919 to acquire oil-rights in the Fyzabad district, Trinidad. The Anglo-French Exploration Co. and the British-Borneo Petroleum Syndicate, are largely interested. G. R. Airth and Walter Maclachlan are the managing directors. The original capital was £200,000, and this was increased to £400,000 in May, 1920. Three heavy rotary drilling plants have been put to work, and the programme for the period to September 30 of this year provides for the drilling of eleven wells. Wells No. 1 and 2 have been producing regularly; No. 1 is to be deepened to the lower oil-sands; production at No. 2 is impeded by faulty tubing. No. 3 came in on November 6 last, and gave an initial flow of about 100,000 barrels in a few hours. The flow was then checked by the well sanding up. This big flow was far greater than expected, and the dam, which was constructed for the storage of only 50,000 barrels, gave way and the oil was lost. The well has since been brought in again, and the production to the end of April other than that lost amounts to 64,769 barrels. Well No. 4 has been capped to control the heavy gas pressure; it is to be drilled into the lower oil-sands. At No. 5 the 10 in. casing has been set and cemented at 1,050 ft. preparatory to drilling into the oil-sands. No. 6, adjoining No. 4, has been drilled into the upper oil-sands; the production from May 23 to the end of April was 20 150 barrels. At No 7 the drilling rig is in course of erection. The total production to the end of April has been 94,006 barrels, equal approximately to 13,400 tons. An arrangement has been made for the sale of the oil production to Trinidad Leaseholds, Ltd., and 80,000 barrels had been delivered at the time of writing the report, May 7. A geological examination of the company's property was made during the latter half of last year by Dr. F. C. P. Mueller-Carlson, and the directors state that his report is of a most satisfactory nature

EDITORIAL

THE ceremony of presenting Sir Robert Hadfield with the John Fritz medal was one of unusual and pleasant significance. It was kindly thoughtfulness that prompted the American societies to instruct their members attending the Engineering Conference held in London last month to form a delegation for making a public presentation of this medal. The John Fritz Foundation was started in 1902 to commemorate the great services to iron and steel metallurgy rendered by the late John Fritz, head of the Bethlehem works in Pennsylvania, and the bestowal of the medal is the highest honour that can come to an engineer from America. Sir Robert, in reply, accepted the medal not entirely as a recognition of his own personal work, but also as conveying an expression of the regard felt by the American engineering profession for the abilities displayed by the British engineers and metallurgists during the war.

REFERENCE is made in the preceding paragraph to the Engineering Conference held in London last month. This was arranged by the Institution of Civil Engineers, and was the first held since the outbreak of the great war. One of the sections was devoted to mining and metallurgy, and here a number of interesting discussions took place. Dr. J. W. Evans dealt with the application of water-power in the development of mineral resources; Mr. R. Nelson described recent improvements in coal cleaning, instancing the action of flotation and table concentrators; Mr. H. Standish Ball read a communication on the Francois cementation process; and Mr. Thomas Crook, of the Imperial Mineral Resources Bureau, presented a paper on the effect of the war on mineral supplies. While these papers did not contain any new material, they served to draw public attention to the present problems in mining and metallurgy, and to demonstrate that mining is an important branch of engineering.

THE collapse of Farrow's Bank and the sentence of Mr. Farrow to four years' penal servitude for the issue of falsified balance-sheets are so much matters of public notoriety that little need be said here. It is to be regretted that a man of such long experience of the iniquities of moneylenders, both regular and irregular, should have attempted to conduct a bank without full experience of the details and without a financial backing that would bring profitable business for the funds deposited with him. While being sorry for the people who lost their money, we are equally sorry that Mr. Farrow did not succeed in his ambition. No doubt the big banks are glad that he has disappeared. At the time of his arrest they advertised extensively that they provided every facility for small depositors, but experience shows that they do not really care for this class of business. The Post Office still gives $2\frac{1}{2}\%$ per year on deposits, and has removed the yearly and total limits in order to attract as much money as possible for public use. The Savings Certificates offer a higher rate of interest than the Savings Bank, but the Post Office limit holds good here. A day may arrive when the Government and the bankers will treat the meanest depositor rather more graciously. Until then there will be a succession of attempts, by honest or dishonest men, to attract the savings of comparatively poor people by offering the advantages enjoyed by their more fortunate fellow-citizens.

ONE or two doubtful projects have been launched publicly or privately during the last few weeks. One revives an old scheme for selling a mixture of chalk and some unspecified ingredient as a substitute for coal. This proposal usually makes its appearance when coal is scarce, whether the scarcity is due to war, railway trouble, or closing of the coal-mines. It seems hardly necessary to refer to this matter here, for no reader of the MAGAZINE is likely to be deluded by the advertisement. Another doubtful scheme deals with a copper deposit in the Shetland Islands. A news agency circulated a paragraph in the daily press announcing the discovery of two copper lodes at Sandwick in the island of Yell, estimated to contain 100,000 tons and 300,000 tons of ore respectively. The secretary of the company wrote to the papers subsequently stating that the deposits are not in Yell but in the Mainland, and modifying the estimate of ore, the implication being that the puffers of the shares "yelled" too soon or too loudly. Many letters have been received by us with regard to this project. Our advice in return has been that inquiries should be addressed to Dr. J. S. Flett, head of the Geological Survey,

at the Jermyn Street Museum. He has an intimate personal acquaintance with the Shetland Islands and their geology. It would be a good chance for a Government Department to enter into financial affairs and tell prospective investors what to expect. As for ourselves we are tired of running the risk of libel actions. It is best that public bodies should take action, as the Surrey County Council did in the case where lemonade " made from Messina lemons " was proved to consist of sugar and phosphoric acid. Even here there were plenty of first-class scientific experts who were prepared to say that the description was justifiable. The MAGAZINE cannot afford either lawyers' fees or the fees of experts practising in the courts.

FATE follows the American Institute of Mining and Metallurgical Engineers. Another so-called crisis has arisen through the resignation of Mr. Bradley Stoughton as secretary. For many years the Institute flourished under the autocratic and beneficent rule of Dr. R. W. Raymond, and under his auspices it became an unrivalled expositor of mining and metallurgical practice. The papers and transactions, through his influence, were of the highest order from both the professional and the literary standpoint, and membership of the Institute was prized accordingly. Before he died the control was wrested from his hands, and subsequently also many modifications in the policy of the Institute were introduced. Of recent years far too many papers have been written and published, and the net for membership has been cast far and wide, without any desire for increased *esprit de corps*, but merely prompted by a desire to increase the revenue of the Institute. The discontinuance of the distribution of papers by means of the monthly bulletin, and the establishment instead of a gossipy monthly paper called *Mining and Metallurgy* was another false step intended for greater publicity and income. We understand that the future of this monthly paper is under serious discussion by the council of the Institute, and that proposals are being considered for its amalgamation with another organ of the profession. In the meantime the reason for Mr. Stoughton's resignation remains a mystery. He says that a secretary should not in any case retain his office for more than ten years, but the wisdom of this view we take leave to doubt. Mr. Stoughton is a capable metallurgist, he is a good tactician and administrator, and he has a sense of humour, and as far as politeness and consideration for others is concerned he is perhaps too polite to some of those with whom he has to come in contact. It is really a pity that he is resigning, and that the council of the Institute cannot adopt a more stable and professional policy.

Statistical Returns

In the last issue we referred to the report by Mr. Hugh F. Marriott on the work at the mines of the Central Mining and Investment Corporation, mentioning that his figures of revenue from the gold output are based on its par value, and that the credits due to the premium are given separately. But for the fact that some other engineers and companies do not adopt this practice, the method would seem to be the obviously and indisputably correct one. The standardization of statistical returns has been referred to in these pages on several occasions, and in many cases improvements in their presentment have been observable during the past few years, but there is still a lack of an agreed system among the mining companies, with the result that the labours of the statistician are unnecessarily complicated. The present is a convenient opportunity for mentioning the matter again, and for glancing through the returns as supplied month by month by the chief companies in various parts of the world.

Taking first the gold mines of the Transvaal, we find that the Central Mining-Rand Mines group report the fine ounces, the estimated value including premium, and the estimated profit on the same terms. The Consolidated Mines Selection, Consolidated Gold Fields, Union Corporation, Anglo-French, Witwatersrand Deep, and Luipaard's Vlei follow the same course. On the other hand, Johannesburg Consolidated and the Albu group do not give the ounces, but report the estimated revenue and profit including premium. They, however, give the estimated price of gold per ton, as do the other groups, so that anyone desirous of finding the figure for the actual output can do so. But it would be simpler for everybody if the figures for the ounces were given, because these are the first obtained when the gold is won, and, anyway, dividing backward does not necessarily give the identical figures. Moreover, uncertainty may exist as to whether the cost of realization has been deducted from the gross revenue or not. In the list of Rhodesian producers, most of the

mines report in ounces, two report in pounds at par, one in pounds at an estimated price of gold, while another does not say whether the pounds represent par value or include premium. In West Africans, Taquah, Abosso, and Ashanti Goldfields report in ounces, Abbontiakoon and Prestea Block A in pounds at par, and Obbuassi in revenue including premium, but without stating the price of gold used in making the estimate. The Indian gold mines give the outputs in fine ounces. The Australasian mines pursue every possible variety of practice. Some give their returns in fine ounces, some in revenue at par, some include specified premiums, and others unspecified premiums; some lump royalties from tributers in one sum with the output from the companies' mines, and these outputs may be at par or may include premium; finally the New Zealand mines give their returns in four-weekly periods and not by the calendar month.

There are a number of other gold mines in various parts of the world under English control or of interest to English shareholders, and most of them report in ounces or in United States dollars. For instance, St. John del Rey gives the par value in pounds and Ouro Preto the ounces, nothing being said of premium in the monthly reports. Plymouth Consolidated and Tomboy, being in the United States, have no premium to help them, so report at par value. Of the Mexican mines, El Oro and Mexico of El Oro report the realized value in United States dollars, and Esperanza and Santa Gertrudis report the profit in United States dollars. The Pato and Nechi companies, operating in Colombia, publish returns of dredging runs of irregular numbers of days in United States dollars. Here, as with the Mexican mines, the gold values are at par, for the companies are not allowed to take advantage of the free markets.

No doubt some companies, in reporting output and profits, prefer to give the full income including premium, so as to make the returns as big as possible; indeed, if the premium were not included a loss would sometimes be shown, and an unpleasant jar would be given to the shareholders. It is naturally argued that from the shareholders' point of view the actual income is what matters. But to the serious student of mining more precise and complete information is necessary, and as its preparation and publication would entail no further time or expense to the several companies, there is no reason why in every case the specific figures for the output should not be given in addition to the revenue derived therefrom.

The Sir John Cass Institute

The delivery of lectures on various aspects of the zinc industry by Messrs. J. C. Moulden and E. A. Smith at the Sir John Cass Technical Institute, to which reference was made last month, has served to draw attention once more to an educational institution in the City of London that deserves to be better known in mining circles than it appears to be. Owing to so many inquiries having been received as to its scope and functions, it is appropriate that something should be said on the subject in these columns.

Sir John Cass was a merchant and alderman of the City of London who flourished about two hundred years ago. He did much for education in his lifetime, and after his death his estate carried on the work. In 1895 a new scheme was put forward by the Charity Commissioners, which provided for the establishment of the present institute. The foundation stone was laid by Bishop Creighton in 1899, and the building was opened by the late Lord Avebury, better known as Sir John Lubbock, in 1902. The institute is in Jewry Street, Aldgate, not far from Fenchurch Street Station. Instruction is given in pure and applied science, and in the arts and crafts. The department of science includes courses in mathematics, physics, chemistry, and metallurgy, and the curriculum is designed to meet the requirements of students who are engaged in the chemical, metallurgical, electrical, and engineering industries. The institute is intended primarily for the evening student, who is occupied in earning his living during the day, but facilities are also afforded for special research work during the afternoons. The fact that the classes are held only in the evenings makes it possible for the institute to enrol among its teachers a number of practical men who have won distinction in their own particular lines, and who, from a sense of duty, are ready to give of their best to those desirous of acquiring knowledge. The head of the institute is Dr. Charles A. Keane, who is well known for his books on chemistry and analysis, some of which he wrote in collaboration with Dr. George Lunge. In the department of metallurgy, the first lecturer was Dr. Guy Bengough, who is known for his researches on corrosion. He

was followed by Mr. C. O. Bannister, who was associated with the firm of Edward Riley & Harbord, and is now professor of metallurgy in the University of Liverpool. Mr. George Patchin, A.R.S.M., M.Inst.M.M., became head of this department of the institute in 1919. He had previously achieved great success as a teacher at the Birkbeck College. Among other members of the present staff the following may be mentioned: Mr. W. A. C. Newman, assistant chemist at the Royal Mint; Dr. O. F. Hudson, metallurgist at the Admiralty research department; and Dr. W. R. Schoeller, chemist to Daniel C. Griffith & Co., who takes the class on mineralogy. In addition to the regular course, special lectures are given every year, Last year three lectures were delivered by Mr. H. Livingstone Sulman, on "Froth Flotation." This year, as already mentioned, Mr. J. C. Moulden is lecturing on "Modern Developments in the Zinc Industry," and Mr. E. A. Smith is lecturing on "Industrial Applications of Zinc." These special lectures are open to outsiders, and many City men have found them helpful and instructive.

The metallurgical course includes a variety of subjects, as will be seen from the following list: General metallurgy, elementary, intermediate, and advanced; assaying; iron and steel; metallography; mechanical testing of metals and alloys; heat treatment of metals and alloys; foundry practice; mineralogy; mechanical drawing for metallurgists; materials of construction and design. These courses include lecture, demonstration, and laboratory work wherever suitable. Additional courses are being considered, to deal with furnace design and construction, and with electric furnaces and smelting. The complete curriculum extends over four years, not including a preliminary year devoted to elementary physics and chemistry, and at the end of that period a diploma is granted to those students who reach the required standard. Other departments of the institute are organized on the same scale, and some of the subjects dealt with are of interest to metallurgists: for instance, Dr. Owen's course on colloids.

In addition to lecture rooms and drawing office, the metallurgical department contains a main laboratory for general analysis, a laboratory for dry assaying and furnace work, a metallography and pyrometry room, a mechanical testing laboratory, and a moulding and casting room for foundry work. The laboratories are well equipped and arranged in the latest manner. The metallography and pyrometry room contains photomicrographic outfits, polishing machines, visual microscopes, galvanometers and millivoltmeters, thermo-couples, resistance pyrometers, differential apparatus and electric furnaces for ascertaining critical temperatures, thread recorder, Callendar recorder, and dark room. The mechanical testing laboratory, which was endowed by the Goldsmiths' Company in 1914, is equipped with a 30 ton Buckton testing machine fitted with autographic recorder, an Izod impact testing machine, a Brinell hardness machine with Ludwick cone attachment, a Sankey bending machine, a Shore scleroscope, and a cement testing plant.

The institute achieves success and supplies instruction which is greatly appreciated by a great variety of students. The further expansion of the sphere of usefulness of the metallurgical department is the ambition of Mr. Patchin, and we trust the profession will give him encouragement and back his efforts in a practical way.

St. John del Rey

As usual, Mr. George Chalmers' yearly review of operations and conditions at the Morro Velho gold mine in Brazil, operated by the St. John del Rey Mining Company, is replete with interest. Few companies or managers give such elaborate details of their work. There is no suppression of the difficult problems, and the reasons for deciding on any particular policy are fully disclosed and candidly discussed. And there have been, and still are, many difficult problems. For instance, the ore is arsenical and not amenable to what may be considered standard treatment. The ore and walls do not stand well, so driving and sinking must be done off the lode, incline shafts are not desirable, and close filling after stoping is necessary. The ore-body is in the nature of a narrow elongated pipe pitching in a vertical plane, so that prospecting for it at depth by diamond drill from the surface is quite out of the question. As for sinking a deep-level vertical shaft, it happens that at the period when such a policy might have been adopted with success, in the light of subsequent knowledge, the ore was showing signs of becoming poorer in depth, and any policy other than following the lode would have been financially unsound. Thus we have the series of vertical shafts and connecting tunnels characteristic of St. John

del Rey, which are so inexplicable to those who have not read Mr. Chalmers' reports since he took up the management thirty years ago.

The problems that have faced Mr. Chalmers during the last few years have arisen from two causes, first the flattening of the pitch, and second the unbearable heat at the bottom workings. As regards the pitch, this was approximately 45° at a vertical depth of 3,000 ft. As the workings went down, the pitch has gradually tended to flatten, and at 5,500 ft. the ore-body is at about 30° with the horizontal. This alteration, of course, makes the successive tunnels longer, so that below the 22nd horizon, 6,126 ft. vertically below the outcrop, there will be no alternative but to sink incline shafts to follow the pitch. At the present time the deepest development work is at this horizon. At first the ore exposed proved somewhat disappointing, but it was felt that it was just possible that the main ore-body had not been struck, that the flattening had been greater than calculated, and consequently that parts of the lode unpayable in the upper levels had been intersected by the tunnel and winze. This uncertainty existed when the annual report was circulated. At the meeting of shareholders the Chairman had the great good fortune to be able to announce that the true lode had been discovered in a cross-cut and that the gold assays are as good as ever.

The other present difficulty to which reference is made arises from the heat at depth. This question has received the close attention of Mr. Chalmers for the last ten years, and has formed an important feature of his yearly reports for some time past. The whole matter is crucial to the future of the mining industry in all parts of the world, and the experience at this mine should be discussed in conjunction with such cases as the City Deep. In 1913 Mr. Eric Davis, one of the staff at St. John del Rey, commenced a study of temperatures with the dry-bulb and wet-bulb thermometers. By experience it was decided that the wet-bulb temperature in the stopes should not be greater than 82° F., and it was calculated that to get these conditions the initial moisture content of the air entering the mine should be not more than about 50 grains per pound of dry air. This content corresponds to a saturated condition at 45° F. A refrigerating plant was then ordered, capable of cooling 80,000 cu. ft. of air per minute to a temperature of 43° F. It is not necessary here to go into details of this plant, for particulars were given in the MAGAZINE for October, 1919. This plant would have been erected long ago if it had not been for the war. The delays in delivery were unavoidable under the circumstances, but they caused great anxiety at the mine. Eventually the machinery and outfit arrived last year, and the plant was started at the beginning of December. In the meantime, however, the development of the mine in depth became almost impossible, and the stoping operations became difficult. The workmen could not stand the heat, and many of them left, with the consequence that the output was reduced. The most serious difficulty arose in connexion with the driving of the tunnel on the 22nd horizon, and the sinking of winze No. 31 from the horizon above to meet it. The conditions of working may be gleaned from the fact that the rock temperature in these dead ends was 117° F. The heat was sufficient to interfere with the electric motors driving the fans, and altogether there was some doubt whether the human being could achieve the connexion of tunnel and winze. Mr. Chalmers rightly praises Captain Watts and his helpers for persisting in the driving of the tunnel under these adverse circumstances. The connexion was eventually made on January 2; and the circulating current was then established. As the cooling plant had been started a short time before there was no difficulty in continuing the work and developing the ore-body at this depth. It is clear, however, that if the cooling plant had not arrived in time there would have been no alternative but to stop development in depth and realize the ore reserves. As it is, the cooling plant makes it possible to apply the winding and other machinery already provided for sinking and working to a vertical depth of 7,500 ft. In connexion with this brief notice, it is desirable to read the precis of the last yearly report, printed on another page, which is accompanied by a drawing showing the bottom workings. Owing to the small size of our page it is not possible to reproduce the full plans and elevations accompanying the report. Those of our readers who are interested should write to the company for a copy of the report, or call on the ever-obliging Mr. Kup, the managing director, and inspect the model of the ore-body and the various elaborate working drawings showing the form of the ore-body and the method of development and mining.

REVIEW OF MINING

Introduction.—The settlement of the coal dispute has come at last, and the mines are gradually resuming operations. The steel makers and the engineering works are hoping that coal will be plentiful and reasonably cheap. If such hopes are verified, the consumption of metals will once more be revived, and the producers of copper, lead, tin, and zinc will benefit.

Transvaal.—The dividends declared on the Rand for the half-year January to June are given in the accompanying table. The figures are lower than those for the previous half-year, but as the last-named figures were rather greater than might have been expected, the market was quite prepared for the fall.

† On old £1 shares. *a* Scrip distribution equal to 16%. *Free of tax. ‡Also Scrip. **On old £1 shares.

The total dividends of Transvaal gold mining companies declared during the half-year were £3,238,838, of which £2,260,222 came from companies operating in the Far East Rand, and £978,616 from the older parts of the Rand. The dividends declared by companies outside the Rand were £37,563.

Last month we quoted Mr. H. F. Marriott's report on the conditions at the mines of the Central Mining-Rand Mines group. One of his points as regards efficiency related to the obsolete law that natives must not start work each day before the white overseers give instructions, and that they must leave in front of the white man. He pointed out that under this regime the actual working time of the native averaged only five out of the statutory eight hours. It is now announced that the Mines Department is embodying in the regulations a clause giving permission for the establishment of night inspection shifts with the object of enabling the natives to start work earlier. Evidently Mr. Marriott's protest has borne fruit.

The sinking of No. 2 shaft at West Springs is to be suspended for a time and the ground below is to be explored by bore-hole. The reason for the suspension is not given, but presumably the water trouble referred to in the yearly report is the cause. In the meantime development from No. 1 shaft is to be intensively pushed and connexion made with the workings started from Springs mine, so that an ore reserve may be created at the earliest possible date.

At Springs mine the ore reserve has been substantially augmented recently, and the directors have decided to purchase additional plant so as to increase the monthly tonnage from 40,000 to 50,000.

The No. 7 shaft at Geduld reached the reef at a depth of 2,450 ft. on June 19. The assay-value was 0·6 dwt. over 35 in. Though this figure is low, it does not worry the company, because it happens that an extensive area of unusually high-grade ore has already been developed in the neighbourhood of the shaft. In the yearly report recently issued it was stated that development in this area had proved 4,215 ft. in ore, of which 66% was payable, averaging 16 dwt. over an estimated stoping width of 66 inches.

Rhodesia.—The output of gold during May was 48,744 oz., as compared with 47,858 oz. in April and 46,266 oz. in May of last year. The value is reported at £225,841, as against £282,396 in April, the divergence being due to the usual erratic manner in which the premium is credited in Rhodesia. Other outputs during May were: Silver, 12,806 oz.; coal, 44,688 tons; chrome ore, 5,700 tons; copper 266 tons; asbestos, 2,345 tons; arsenic, 8 tons; mica, 6 tons; diamonds, 8 carats.

During 1920 the ore milled at Shamva amounted to 609,509 tons, and the yield of gold was 96,718 oz. The assay value of the

ore was 3·6 dwt. per ton, of which 3·26 dwt. was extracted. The gold sold for £538,887, and the working profit was £223,526, out of which £180,000 was distributed as dividend, being at the rate of 30%. The reserve is estimated at 1,981,250 tons, averaging 4·1 dwt., as compared with 1,982,000 tons averaging 4·31 dwt. the year before. Eight additional Nissen stamps and one tube-mill have been erected during the year. With regard to the general mining policy, Mr. Cyril E. Parsons, the consulting engineer, says that the future of the property and the prolongation of its life still depend largely on the possibility of profitably removing and treating the large tonnage of low-grade overburden, so that the better ground lying underneath can be successfully mined; any attempt to mine without removing the overburden would in his opinion cause disastrous falls of ground.

In speaking at the meeting of Fanti Consolidated, as reported in the MAGAZINE last month, Mr. Edmund Davis announced the sale of the chrome interests. He stated that the new discoveries of ore in Rhodesia and competition from other parts of the world would lead to diminished profits. Thus the control of the chrome market, so long associated with Mr. Davis's name, comes to an end. The deposits discovered two years or more ago in Rhodesia are very extensive. They are being developed by Rhodesia Base Metals, Ltd.

Nigeria.—The Bisichi Company has received advice from its engineer to the effect that prospecting operations on one of the leases have given excellent results, four million cubic yards of ground being proved to contain approximately 5,000 tons of cassiterite. The whole of the area has not yet been tested, and it is believed that further prospecting will continue to increase the reserve.

The Nigerian Consolidated Mines was formed early in 1920 to acquire a number of tin properties in the Rayfield, Jemaa, and Womba districts from Mr. W. E. Thomas, who became managing director. As recorded in our issue of April, Mr. Thomas died suddenly of pneumonia. The report for the period from the registration of the company to February 28 shows that the output of tin concentrate was 233 tons, which was satisfactory considering that the properties had not been brought into full working order. The accounts show credits of £24,308 from the sale of concentrate, but the year ended with an adverse balance of £3,843. Owing to the fall in the price of tin, operations have been discontinued for a time, though some tributing is being done. The directors write hopefully of the prospects of increasing the output when conditions improve.

Australia.—The Australian Court having consented to a suspension of the award of higher wages and a modification of the working hours, the Mount Lyell company finds it possible to continue work. The Wallaroo and Moonta company announces the approaching resumption of operations on a restricted scale. At Mount Morgan the conferences between the directors and the leaders of the trades unions have brought no result so far, and the mine remains closed.

The Great Boulder Proprietary Company has paid a handsome dividend for 1920, but the profits were largely due to the gold premium. The working cost was 41s. 9d. per long ton, as compared with 35s. 8d. in 1919, and 32s. 6d. in 1918. Six years ago the cost was about 24s. per ton. The new property at Norseman has given good results, and substantial profits are expected, providing labour conditions are satisfactory.

Siam.—The Siamese Tin Syndicate made a record in connexion with output during 1920. The three dredges treated 2,200,640 cu. yd., and extracted 937 tons of tin concentrate, the previous highest figures having been in 1916. The income from the sale of concentrate was £198,285, and the working profit £45,271, out of which £36,000 has been distributed as dividends, being at the rate of 30%. It will be remembered that the company floated a subsidiary eighteen months ago, called the Bangrin Tin Dredging Company, to deal with alluvial tin ground about five miles north of the company's property. Rails have since been laid and the site for the dredge has been prepared. The dredge has been designed by Messrs. F. W. & R. Payne, but its construction has been delayed by labour troubles in this country, and by the coal strike.

Burma.—The issue of new preference shares by the Burmah Oil Company, to which reference was made last month, proved a great success. Since then the report for 1920 has been issued. The gross profit was £4,891,500, out of which £1,153,800 was written off for depreciation, while the excess profits duty is estimated at £1,900,000. The ordinary shares received £1,543,000 as dividend, being at the rate of 30%. The present company was formed in 1902 as

an expansion of a company of the same name registered in 1886. The chief property is in the Yenangyaung oilfield in the Irrawady valley, and there is every expectation that the ground will continue to yield handsomely for many years yet. A pipe-line 300 miles long takes the crude oil to Rangoon, where refining is done. The company formed the Anglo-Persian Oil Company, and, with the British Government, still holds nearly all the ordinary capital of that company. It purchased the control of the Assam Oil Company, and it operates the property of the Budderpore Oil Company, also in Assam. Among other interests are shareholdings in the United British Oilfields of Trinidad, and a participation, in association with the Anglo-Persian, in exploratory operations in Hungary. In order to obtain material for receptacles for its various products, the company recently joined with the Tata Iron and Steel Co., Ltd., in promoting the Tinplate Company of India, and the works are now in course of erection at Jamshedpur. Electric power plant has been installed on the company's properties in the Yenangyaung oilfield, and power will also be supplied to its neighbours, the British Burmah and the Indo-Burmah Petroleum Company.

In the May issue some particulars were given of a private and informal meeting of shareholders in the Burma Corporation, at which a resolution was passed agreeing to the company purchasing the control of a group of lead manufacturers in this country. Subsequently powerful protests were made by influential shareholders. It has since been announced that these protests have carried weight, and that it has been decided not to proceed with the matter. There is no inherent reason why the proposal should not be a sound one commercially, providing the facts and details are all right ; but the attempt to rush the matter semi-secretly raised the opposition. The way in which the control of Burma Corporation is exercised leaves much to be desired.

Cornwall.—As reported last month, an extensive fall of ground has occurred in the main shaft at East Pool. The cables were broken, so that the electric pumps were put out of action. The old Cornish pump at Agar shaft has not been able to cope with the water. The position thus became serious, not only to East Pool, but to the adjoining mine, South Crofty. The directors and engineers of the two mines have met several times, with a view to devising some joint action. The engineers, Mr. M. T. Taylor and Mr. Josiah Paull, are now engaged in considering methods for combating the water.

Canada.—The Chairman of the Mining Corporation of Canada, at the recent meeting of shareholders, referred to the acquisition of a majority interest in the Flin-Flon copper-gold property in Manitoba. He stated that 16,000,000 tons of ore had been proved, with an additional probable 9,000,000 tons. He also claimed that the sampling of recent workings showed a content 30% higher than previous figures. Details of these new estimates are desirable before they are likely to arouse much interest among mining men.

United States.—A proposed new mining law is to be submitted to Congress. It has been drawn up by the aid of the mining societies and the Bureau of Mines, and the committee has had the advice of mining lawyers. A notable feature of the proposal is the abolition of the " apex law " as far as mining claims recorded in the future are concerned. Another feature is the discarding of the principle of actual discovery of a mineral deposit as a prerequisite to the location of a claim, though it is provided that discovery must be made before a claim is patented.

The suspension of copper production in the United States is well known, but the slackness of the iron and steel trades has not until recently been indicated by the issue of tangible figures. It is now announced that the shipments of iron ore from the Lake Superior mines to the smelters for the five months to May 31 last was 2,770,238 tons, as compared with 7,206,939 tons for the same period during 1920.

Mexico.—The report recently issued in the United States to the effect that the Mexican oilfields would be exhausted in the course of a year or two was not believed in this country, where it was held that the report was written for some political or similar purpose. Another report has since been issued from the same source in which it is stated that the potential production of the Mexican oilfields is almost unlimited. This is probably rather a better guess than the first, but it is equally vague and unsatisfactory.

The political position with regard to Mexican oil, as outlined in the foregoing paragraph, has been publicly exposed by the action of the Standard Oil in threatening to cease production and exports from its

properties in Mexico. The Mexican Government had announced the imposition of a duty on oil exports, anticipating a threatened discriminating import duty into the United States. Some doubt existed as to whether the Mexican Government would enforce this duty. The daily papers allege that the United States Government will take steps to protect the American citizens thrown out of work by the cessation of the Standard Oil's activities. The other oil companies operating in Mexico declare that they are pleased at the Standard Oil's attitude, but it must be remembered that there is a political aspect as between the United States and Mexican Governments, and that the Standard Oil's tactics go further than a mere trading ruse.

Ten years ago the directors of the El Oro Mining and Railway Co. decided to form a local subsidiary company for the purpose of testing other properties in Mexico. This subsidiary has already done much work in the States of Zacatecas, Mexico, Hidalgo, and Jalisco. To provide further funds the El Oro Company has recently subscribed for 50,000 additional shares of 10 pesos each, and is issuing 49,500 shares among shareholders as a bonus dividend, being at the rate of one share for every 25 El Oro shares.

Colombia.—A company has been formed, called the Colombian Proprietary Gold Mines, Ltd., to acquire alluvial gold properties on the Llantin river, a tributary of the Saija, about 70 miles south of the port of Buenaventura. Mr. T. J. Ive is chairman, and Messrs. Inder, Henderson, & Dixon are the consulting engineers, while the British Platinum & Gold Corporation has underwritten the present issue of shares. The vendor company is the Compania Minera de Santa Rosa, of which Mr. Henry J. Eder, of Cali, Colombia, is the largest shareholder. A report has been made by Mr. A. G. Davidson, who has been associated with the consulting engineers for some years. The developments have warranted the placing of a contract with Messrs. Lobnitz & Co., Ltd., of Renfrew, for the construction of a dredge having a capacity of 60,000 cu. yd. per month.

The British Platinum & Gold Corporation has issued a statement showing that since the dredge on the Opogodo property was put to work in December last a total of 966 oz. of platinum, together with 280 oz. of gold, had been recovered up to May 21. A model of this dredge was shown at the Colombian Government's stand at the Rubber and Tropical Products Exhibition at the Agricultural Hall. In this dredge a balanced reciprocating screen is used instead of cylindrical screens for removing coarse stones and boulders.

The report of the Oroville Dredging Company, whose assets are now entirely in the form of shares in companies operating in Colombia, gives a brief account of the performance of the dredges operated by the Pato and Nechi companies during the year ended September 30 last. At the Pato property 1,437,600 cu. yd. yielded gold worth $526,267, or 36·6 cents per yard. The operating cost was 13 71 cents per yard. At Nechi 2,135,084 cu. yd. gave gold worth $816,188, or 38·2 cents per yard. The Oroville received dividends of £88,186 and £28,348 respectively from its holdings in Pato and Nechi, and distributed £94,398 among shareholders, being at the rate of 2s. 9d. per £1 share.

Brazil.—The output of gold from the Ouro Preto mines during 1920 was 27,858 oz., obtained from 82,100 tons of ore. The gold sold for £156,490, and the working profit for the year was £16,229, out of which the 10% dividend on the £29,661 preference shares has already been paid. A further dividend on the preference shares of 5%, and a dividend of 5% on the £39,429 ordinary shares have since been paid. Developments have continued to disclose ore.

Russia.—Mr. Leslie Urquhart delivered one of his characteristic speeches, displaying a thorough knowledge of Russian conditions from both the political and mining point of view, at the meeting of the Russo-Asiatic Consolidated, held on July 6. This company was working and developing many important properties before the revolution, but these properties have been nominally confiscated by the Bolsheviks. One of these days Mr. Urquhart will induce the powers that be to respect the rights of property, to the benefit of Russia and of all those desirous of working and trading within her boundaries.

Spitsbergen.—In May we mentioned that the Northern Exploration Company was offering £150,000 Secured Notes to shareholders with the object of keeping the organization alive. It is now announced that £61,610 of these Notes have been allotted. This has enabled the company to pay off its debts, and to dispatch a small expedition this summer.

THE IRON AND STEEL INDUSTRY OF INDIA

By J. COGGIN BROWN, O.B.E., D.Sc., M.Inst.M.M., F.G.S.,
Officiating Superintendent, Geological Survey of India.

This article is written with the permission of the Director, Geological Survey of India.

(*Concluded from page 347, June issue.*)

The Bengal Iron Co., Ltd.—This company was registered in December, 1919, with an authorized capital of £2,500,000 to acquire the Bengal Iron & Steel Co., Ltd. The works are situated at Kulti in Bengal on the East Indian Railway, 142 miles from Calcutta. It has already been shown how the latter company, founded in 1889, was the lineal descendant of the Barakar Iron Works Co., Ltd., which was started in 1875. In 1889 the plant consisted of two small open-top furnaces, only one of which was worked, for which the blast was heated by coal in pipe stoves, and one blowing engine with its complement of boilers which were entirely fired by coal. The production of pig iron in 1889–90 was about 9,000 tons per annum, and was disposed of to Government establishments either in that form or in the shape of castings. The foundries then covered an area of 12,300 sq. ft., and the production from them was 3,800 tons per annum. At that time the company did not own its own collieries, but purchased its coal and coke requirements in the open market. The site of the works was chosen originally on account of the close proximity of both coal and iron ore supplies, and for many years the clay ironstone nodules that formed the ores for the furnaces were obtained from a geological horizon in the Gondwanas, known as the Ironstone Shales. This crops out between the coal-bearing Barakar and Raniganj stages, and stretches for some distance east and west of the works. The iron ore was obtained by contract with the local proprietors of bullock carts, and the supply was uncertain in quantity and variable in quality.

The remodelling of the works was taken in hand at once. The two original blast-furnaces were converted into close-top furnaces to enable the gas to be utilized for firing the boilers. At a later date, as they required rebuilding, they were removed and replaced by two modern furnaces. A new furnace was also erected, fitted with three 17 ft. diameter Cowper stoves. During the period up to 1914 steady progress was made; collieries were purchased and developed, namely, Noonodih, in the Jherria field, in 1905, and Ramnagar, 1½ miles distant from the works, and connected with them by a light railway, in 1907. By 1908 several small iron ore areas had been acquired, one of which was at Kalimati (now Jamshedpur), close to the site of the present Tata iron and steel works. With the opening up of the company's mines at Manharpur, in the Kolhan Estate of Singhbhum, in 1910, a constant supply of first-class hematite was assured, for already many millions of tons of high-grade material have been proved, and the use of the ore from the Ironstone Shales was finally discontinued. The outbreak of the war found three furnaces in operation with an annual output of approximately 80,000 tons of pig-iron, each furnace with its four Cowper hot-blast stoves, and the whole plant operated from a modern power-house containing three turbo-blowing engines of a total horse-power of over 4,000. The plant in existence to-day will now be described.

There are four furnaces in operation, a fifth under construction, and twenty stoves for heating the blast; seventeen of the latter are 65 ft. high by 21 ft. in diameter, and three are 55 ft. high by 17 ft. in diameter. On the completion of the fifth furnace the total capacity of the plant will be 175,000 tons of pig iron per annum. The blast is supplied from turbo-blowers of the Parsons type, with a total capacity of 115,000 cub. ft. of air per minute. There are twenty-four Lancashire boilers, fired by waste furnace gas, in two batteries, supplying steam to the blowing engines. The iron ore, coke, and limestone are delivered from railway wagons and raised to the charging hoppers by two steam and electric hoists. In the case of No. 5 furnace, a Brown Hoisting Co.'s charging apparatus has been provided. The slag is removed in Dewhurst ladles and taken to the tip in a molten state.

The coking plant consists of three batteries each of thirty-four Simon Carves by-product ovens, with an out-turn capacity of 130,000 tons per annum, complete with recovery plant for coal tar and ammonia, and

also a sulphuric acid plant. A fourth battery is under construction which will raise the total output to 200,000 tons per annum. The present raisings of coal from the company's collieries (Khendwa and Ramnagar in the Raniganj field and Noonodih in Jherria) are about 150,000 tons per annum, but are being increased to 250,000 tons. The requirements of the coking plant are drawn from these and other sources. The coal is discharged from railway wagons into hoppers, whence it is elevated to the crushing machines and thence to the storage bunkers. It is compressed before entering the ovens.

The waste heat from the ovens passes to a battery of boilers, where it is used in raising steam for the electric generating plant, which has a capacity of 2,500 kw. and provides power and light throughout the works, to the Ramnagar colliery, and to the pumping station at Monberia on the Barakar River.

The area occupied by the foundries has increased from 12,300 sq. ft. in 1890 to 175,000 sq. ft. to-day. This department comprises pipe foundries, railway sleeper and chair foundry, general casting foundry and brass foundry, together with pattern shops, etc. Pipes are made in dry sand moulds and vertically cast. One plant is fitted with hydraulic and the other with electric power. Flanged pipes of all sizes for steam or water mains are made. During the war the company supplied many miles of pipes for Mesopotamia and the North-West Frontier, in addition to 20,000 tons of high-grade ferro-manganese made from Indian ore and dispatched to America, France, and Italy. Large quantities of railway sleepers were also supplied for extensions in various military zones. The railway sleeper foundry is fitted with moulding machines for making both plate and bowl designs.

In the general foundry all kinds of castings up to 10 tons in weight are manufactured, including columns for buildings and mills, straining posts and sockets for fencing, mortar mills, road rollers and machinery castings, ornamental columns, lamp-posts, railings, etc. The foundries are capable of turning out 60,000 tons of castings per annum divided as follows: pipes 15,000 tons, sleepers and chairs 30,000 tons, general castings 15,000 tons.

The Bengal Iron Co., Ltd., to-day employs about 100 Europeans and 15,000 Indians, and every effort is made to cater for the physical well-being and comfort of both. A modern hospital administers free medical treatment. Foodstuffs are issued at cost price, while schools for boys and girls have been built and are principally financed by the company.

Brands of Indian Pig Iron.—The typical composition of the iron ores and fluxes used by the two companies producing pig iron in India to-day are given in the tables on the opposite page.

Dr. A. McWilliam, in the *Journal of the Iron and Steel Institute*, 1918, pp. 451–68, says of the pig iron produced by the Tata Iron & Steel Company: "The series of pig irons produced contain about 0·4% of phosphorus, and can fairly regularly be kept at less than 0·05% of sulphur with less than 1% silica for making basic open-hearth steel, the manganese being brought up to over 1% by the addition of small quantities of manganese ore to the blast-furnace burden. Nos. 1, 2, 3, and 4 foundry pig irons are also made as required."

Indian pig iron in general compares favourably in quality with the best English and Scotch foundry irons, and the special brands which are made by both the producing concerns are superior to any iron imported into India, with the exception of hematite iron. In this connexion it should be mentioned that there is available in India a small output of high-grade coke that could be used if necessary, in conjunction with special ores, to make hematite pig iron equal to the best brands.

The Mysore Government's Charcoal Iron Works.—The Government of the State of Mysore has a blast-furnace nearing completion at Benkipur, where the iron ores of the Bababudan Hills in the Kadur district will be smelted with charcoal. The timber is to be obtained from the great forests of the Shimoga and Kadur districts, and to be treated in a modern wood-distillation plant at Benkipur. It is proposed to manufacture calcium acetate, wood alcohol, and possibly calcium carbide as by-products. The estimated cost of the works is approximately £630,000. The plant is being constructed by the Tata Iron & Steel Co., Ltd., and the company has also been appointed managing agents for a period of twenty-five years.

The Indian Iron & Steel Co., Ltd.—This company was registered in March, 1918, with an authorized capital of Rs.3,00,00,000, subsequently increased to Rs.3,01,50,000 (£2,010,000). Two blast-furnaces with an estimated output of 110,000 tons of pig iron, or 73,000 tons of ferro-manganese, are being

put up at Asansol on the Raniganj coalfield. A large part of the plant has arrived at the site and is being erected now. Development work at the company's mines in the Singhbhum district has proved very large ore reserves, and it is stated that over 100,000 tons are already mined. About 5,000 persons are employed at present.

NEW IRON AND STEEL WORKS.—The establishment of two new iron and steel works in India has passed the stage of consideration, and though it is not permissible at this juncture to give any details about them, it may be stated that very large iron ore reserves have been developed on the concessions granted to the promoters, and supplies of coking coal are assured. Both these raw materials come from the same districts as those drawn upon by the existing companies. The new works may be located as Chandil on the Bengal–Nagpur line between Sini and Adra, and at Manharpur, respectively.

SUBSIDIARY INDUSTRIES.—A great deal of the new plant now under erection at the Tata Iron & Steel Works is intended to supply semi-finished steel to subsidiary industries which are now commencing to grow up at Jamshedpur and other places in India. Among these the following may be mentioned :—

(i) Galvanized Iron. It is anticipated that the production of sheets for this purpose will have commenced within the next twelve months, and in the meantime the smelter of the Indian Zinc Co., Ltd., with a capacity of 10,500 tons of spelter and 25,000 tons of sulphuric acid per annum, is being built. The concentrates for the smelter will be obtained from the Bawdwin mines of the Burma Corporation, Ltd. The potential market for galvanized sheets in India may be judged from the fact that in the fiscal year ending 1914, the imports of these articles into the country amounted to 277,595 tons, valued at £3,584,957.

	Pig Iron.	Ferro-Manganese.	Steel.
1916	244,710	1,843	131,292
1917	248,132	1,475	162,711
1918	248,018	13,223	182,269
1919	307,374	2,650	186,901
1920	317,639	1,183	156,240

(ii) Tinplate. The Tinplate Co. of India, Ltd., has been formed to take up the manufacture of this article in India, and the necessary bars or sheets will be purchased from the Tata Company. The Burma Oil Co., Ltd., alone is said to require some 50,000 tons of tinplate per annum for the containers in which some of its products are marketed.

(iii) Cables. The reduction works of the Cape Copper Co., Ltd., which are capable at present of producing 250 tons of copper per month, are only 15 miles from Jamshedpur. It is proposed to establish a cable company which will make use of steel wire from the Tata mills and copper from the Rakha Hills smelter for this purpose.

(iv) Refractories. Reference has already been made to the Kumardhubi Silica & Firebrick Co., Ltd., in which the Tata Iron & Steel Co., Ltd., holds a large interest. In a similar manner the Bengal Iron Co., Ltd., is pursuing a progressive policy in regard to subsidiary industries in the vicinity of Kulti, and being a large shareholder in the Bengal Firebrick Syndicate is thereby certain of a regular supply of the numerous refractory materials required in its works, and at the same time assures the firebrick works of a steady market for a large proportion of its total out-turn.

(v) Castings. The Bengal Iron Co., Ltd., also owns one-half of the capital of the Eastern Light Casting Co., Ltd., which is erecting large foundries for the manufacture of light castings such as rain-water pipes, rice bowls, etc.

(vi) Miscellaneous. Other subsidiary industries, the establishment of which is being considered in various parts of India, include the manufacture of enamelled ware,

wheels and railway rolling stock, special steels, agricultural implements, ship and boiler plates, machinery for tea factories, jute and cotton mills, collieries, etc.

INDIAN IRON ORES.—The following data are taken from the annual and quinquennial reviews of mineral production in India, unless otherwise stated, and the interested reader is referred to them for fuller details. They form part of the Records of the Geological Survey of India.

Indian iron ores of economic importance may be classified as follows :

(1) Banded rocks composed of magnetite-hematite-quartz schists, associated with cherts, jaspers, and other rocks of Archæan age known as the Dharwars, which are now believed to be the oldest rocks wherever they occur in India. In these silica-iron ore rocks the latter constituent is occasionally concentrated into lenticular bodies of great size. These deposits are comparable with those of the Lake Superior region, Brazil, and other parts of the world, where similar geological conditions prevail.

(2) Bands and nodules of clay ironstone found in shales between the coal-bearing Barakar and Raniganj stages of the Gondwanas.

(3) Surface and sub-surface ores due to the segregation of iron oxide in the superficial deposits formed by rock weathering in tropical climates. These are generally found about the outcrops of the Dharwarian hematite schists, but they occur also in rocks of later geological periods.

The deposits of class (1) furnish the ores which are being smelted to-day, or which it is proposed to reduce in the near future. Those of class (2) supplied the ore in the early days of modern smelting in Bengal, but their use has been discontinued. The ores of class (3) were worked by the native smelters to some extent in the past, but they are only employed for special purposes on a small scale at present, for example by the Burma Corporation, Ltd., as a flux in lead-ore reduction, and there are no reliable estimates of their total extent.

The best known examples of class (1) are :

(*a*) The deposits of Singhbhum and the feudatory States of Orissa.

(*b*) The deposits of the Chanda, Drug, and other districts of the Central Provinces.

(*c*) The deposits of the Kadur district of Mysore.

(*d*) The deposits of Goa and Ratnagiri.

SINGHBHUM.—This is the name given to a district with an area of about 3,900 square miles which lies in the south-east of the Chota Nagpur division of the Province of Bihar and Orissa. It forms part of the southern fringe of the Chota Nagpur plateau. The eastern portions are comparatively open, but elsewhere it is very hilly. The ranges have a general maximum height of about 2,000 ft., which is exceeded by the isolated peaks. The Government estate of Kolhan, where very large deposits of iron ore occur, is in the south-west, while the estate of Dhalbhum lies to the east. Singhbhum is bounded on the west by the Gangpur State, which contains important manganese and limestone deposits, and on the south by the feudatory States of Orissa known as Mayurbhanj, Keonjhar, and Bonai. Geologically, its most interesting feature is a great batholith of granite which has lifted up the Dharwar phyllites and schists. (See map.) A portion of the southern lobe of the granite is included within the boundaries of Mayurbhanj. The chief iron-ore deposits of this State lie within the Dharwar rocks to the east of the batholith and between it and the main mass of the granite traversing the States to the south. The Singhbhum iron-ore deposits and the iron-ore ranges recently discovered in the Kolhan estate occupy roughly a similar position to the west of the batholith. Before describing the iron ores in greater detail it may be mentioned that Singhbhum is a highly mineralized region. Close to the northern margin of the batholith, and extending further to the south-east and west, is the well-known copper belt, a line of workings made by the ancients in their search for copper ores. The Rakha mines of the Cape Copper Co., Ltd., are close to the extreme north-eastern lobe of the batholith. Several miles to the north there is a large intrusion of dolerite now altered to epidiorite, known as the Dalma trap. At intervals along the copper belt there are small lenticular bodies of magnetite-apatite rock. At Kalimati, 5 miles north of the granite, wolfram occurs in quartz veins. Nearer the Dalma trap argentiferous galena has been found at Dhadka. In addition, various auriferous quartz lodes are known, while chromite is associated with peridotites to the south-west of Chaibasa. The geological structure and ore deposits of this interesting region have been described by V. Ball, J. Malcolm Maclaren, L. L. Fermor, C. M. Weld, and H. C. Jones, to all of whom the writer is indebted.

COALFIELDS

A	Raniganj.	E	Karanpura.
B	Jherria	F	Auranga.
C	Ramgarh-Bokaro	G	Hutar.
D	Giridih.	H	Daltonganj.

The main line of the Bengal-Nagpur railway from Calcutta to Bombay crosses Singhbhum from east to west. At Sini junction it is joined by a line running down from the Bengal coalfields. The new railways under construction to open up the iron ore deposits are indicated on the map.

The iron ore deposits that have been exploited for the longest time are those of Pansira and Buda Hills, leased by the Bengal Iron Co., Ltd. The mines are situated about 12 miles and 8 miles respectively south-east of Manharpur station on the Bengal-Nagpur railway, with which they are connected by a narrow-gauge line. The ore takes the form of veins and bodies of hematite in banded iron ore-silica rocks. Many millions of tons have been proved, and the following is a typical analysis: Fe = 64·00; Si = 2·10; Mn = 0·05; P = 0·05.

With these deposits as a starting-point, further prospecting has led to the discovery of iron ore ranges, which are believed to continue for forty miles in a south-south-westerly direction into the Keonjhar State, only a portion of which has been examined up to the present time. The most important range has been surveyed for about 10 miles. It rises some 1,500 ft. above the surrounding plain and its top is formed of good iron ore almost without a break. Another parallel line of hills has been traced for 7 miles, in which the iron ore occupies the same position. In the southern portion it is as good and continuous as in the adjoining range, but in the north replacement is less complete. In a third range the ore is confined to patches which are, however, of considerable importance. To the west of these ranges there are more irregular patches of ore occupying the tops of the hills. These hematites usually appear to average about 64% of iron, with phosphorus ranging between 0·03 and 0·08, or, in some cases, to as high as 0·15. The sulphur content is usually below 0·03. Titanium is also said to be found occasionally in the ore, usually either as a trace or in very small quantities. Samples from the better parts of the deposits contain as much as 68 or 69 % of iron. Although comparatively little work has been done hitherto by the concessionaries, enough is known, according to Sir Henry Hayden, to justify the belief that the quantities available will run into hundreds—possibly into thousands—of millions of tons. A branch of the Bengal-Nagpur Railway now under construction from Amda to Jamda will open up part of this region.

Mr. H. C. Jones, of the Geological Survey of India, who is now making a detailed investigation of these deposits, has shown that the rocks generally consist of shales or slates and phyllites, with beds of sandstone, quartzite, and hematite quartzites. The latter form the main part of the iron-bearing series. The ore-bodies are believed to have been derived from these rocks by local enrichment, largely by the leaching of silica and to a less extent by the introduction of iron oxide.

The iron ore deposits of Mayurbhanj, first noticed by the Indian geologist Bose, are great lenticular leads or bodies of hematite, with small quantities of magnetite associated with banded quartzites and quartz-iron ore rocks. They are intimately connected with granite on the one hand, and granulite rocks of the charnockite type on the other. About a dozen ore-bodies have been located in this State, which are now estimated to contain some 39,400,000 tons of non-titaniferous ores of 60 to 67% of metallic iron. (See C. P. Perin: "The Recent Development in the Iron and Steel Industry of India": American Iron and Steel Institute, October, 1920, p. 5.) The more important ones are the following:

(*a*) At Gurumaishini, this hill mass rises 3,000 ft. above sea-level. The ore deposits occur in three parallel and separate leads, measuring 7,000, 5,500, and 3,000 ft. respectively in length and varying from 300 to 700 ft. in breadth. The total area is estimated at 19 millions of square feet, and the total quantity of ore at many millions of tons. The average composition of the solid ore is Fe = 64·33; P = 0·075; S = 0·021; SiO_2 = 1·64. A great deal of "float" ore of somewhat lower grade (Fe = 61·5) exists. The iron ore mines from which the Tata Co. draws its present supplies are at Gurumaishini.

(*b*) At Okampad, a single great lens of iron ore, 12 miles to the south-south-west of Gurumaishini, covers an area of 300,000 sq. ft., and exhibits at one point a scarp 300 ft. high. There are also two smaller outliers and a large area of rich "float" ores. The average analysis of four samples gives the following results: Fe = 63·11; P = 0·029; S = *nil*.

(*c*) At Badampahar, 8½ miles to the south-west of Okampad, rises the peak of

Badampahar, elevation 2,706 ft. Here there is another single great ore-body, approximately 3,000 ft. long by 500 ft. in breadth, which with many smaller outliers occupies the crest of the hill. Outcrops of massive ore have been measured through a vertical distance of 600 ft. A broad-gauge extension of the Gurumaishini Railway is now under construction from Onlajori Station on the Tatanagar-Gurumaishini branch, to open up the Okampad and Badampahar deposits, and preliminary operations are in progress to develop the latter.

There are indications that similar geological conditions may exist in the Pal Lahara State of Orissa, which is separated from Mayurbhanj by the Keonjhar State.

Chanda District, Central Provinces.—The deposits form well-marked bands associated with the Dharwar rocks. The ore is usually a very high-grade hematite. At least ten separate deposits have been located, and some of them are of large size. The two best known are at Lohara, where the ore forms a hill nearly half a mile long, 200 yards wide, and 120 ft. high, and it has been traced for a further distance of 2½ miles; and Pipalgaon, where there is a very fine mass of red hematite. The Lohara deposit is leased to the Tata Iron & Steel Co., Ltd., by whom it is held in reserve, except when small quantities of this quality of ore are wanted for special purposes. The grade of the ore may be judged from the following analyses:—

Lohara: Fe = 69·21; S = 0·012; P = 0·005; SiO_2 = 0·82.

Pipalgaon: Fe = 71·05; S = trace; P = trace; SiO_2 = 4·5.

Drug District.—The iron ores form conspicuous hillocks rising above the level of the surrounding country. The most important of these is a ridge including the Dhalli and Rajhara Hills, which extends for 20 miles and attains heights of 400 ft. above the plain. The ores are associated with phyllites, and are often of a banded quartz-iron ore type, but in places thick lenticular masses of comparatively fine hematite occur. Mr. C. M. Weld proved 2½ million tons by diamond drilling in the Rajhara mass. An adjoining deposit is assumed to contain 7½ million tons, making a total of 10 million tons, carrying 67 to 68% of iron with 0·06 to 0·09% of phosphorus.

Similar iron ores are now known to have a very considerable extension into the Bastar State to the south, and they are said by Mr. C. P. Perin to carry a tonnage of from 20 to 30 times that now reasonably accurately known.

Mysore.—Smeeth and Iyengar give particulars of these deposits in *Mineral Resources of Mysore*, 1916, p. 65. Iron ores are widely distributed in Mysore, but are very variable in character, and in comparatively few places are abundant or pure enough for modern operations. The best known ores are those of the Bababudan hills in the Kadur district. The crest of this horseshoe-shaped chain of hills is formed nearly entirely of banded quartz-iron ores, largely hematite with some magnetite. The various ore fields are separated by intrusive diorites, often altered into ferruginous clays, or patches of soil and jungle, or quartzites, where the overlying series has been denuded away. A great many million tons of ore exist in this region, but in widely separated patches difficult of access. The following tentative data refer only to one small patch known as the Kemmangundi field, and are believed to be conservative. The area is about 50 acres and the surface conditions are expected to continue to 50 ft. or more in depth. Taking an average depth of only 25 ft., the total tonnage is estimated at 4,000,000 tons of an average composition of Fe = 57; SiO_2 = 2; S = 0·05; and P = 0·08. This and a smaller deposit in the vicinity are estimated to yield three-quarters of a million tons with Fe = 61 to 62, and P = 0·05, and two million tons with Fe = 56 to 57, and P = 0·09. These are only two deposits out of a large number at distances of from 1 to 10 miles from this point.

On an area of 9 or 10 square miles in the neighbourhood of Kalhattigiri, the ore exists practically at the surface, and Dr. Smeeth has concluded that 3 square miles are occupied by good ore. Assuming that the surface ore extends to at least 10 ft., the amount available is 83,000,000 tons. The outer crusts, say to 3 or 4 ft., would yield 25,000,000 tons, carrying 60 to 65% iron, and the remaining 6 or 7 ft. some 60,000,000 tons containing 55 to 58% iron with about 8% of combined water. The amount of phosphorus is somewhat high, varying from 0·044 to 0·105%.

Goa and Ratnagiri.—The iron ores of these regions are of Dharwarian age, and crop out in the midst of laterites. At the surface they are mixtures of limonite and hematite with minute crystals of magnetite. At Bicholim in Goa the main ore band has

been traced for 7 kilometres, and is said to vary from 30 to 100 metres in width. The hard ore is believed to be a surface hydrated form of a friable, schistose, micaceous hematite found unaltered at about 50 ft. below the surface. On account of the extent of the outcrops, however, the hard ore is probably available in large quantities. Analyses show that it is of high grade, very low in silica, and with a phosphorus content below the Bessemer limit. The Ratnagiri ores are of the same type.

OTHER ORE DEPOSITS.—Iron ores occur throughout peninsular India in association with the ancient crystalline rocks of which it is built up, but by far the majority of them are so intimately blended with quartz that only a very siliceous low-grade material can be obtained without concentration. These occurrences of quartz-iron ore schist are so common that newly recorded instances of them are generally passed over as matters of very little immediate economic interest. An attempt has been made in the preceding paragraphs to indicate how, during the past few years, more detailed survey work has brought to light distinct ore-bodies of great size and richness, especially in the Central Provinces and Singhbhum, Mayurbhanj, and Orissa. No useful purpose could be served by giving the very lengthy lists of all the iron ore occurrences which are known in practically every province. These have already been collected by T. H. D. La Touche in his annotated index of Indian Minerals of Economic Importance.

COAL SUPPLIES.—The question of the supplies of metallurgical coke which are likely to be required to meet the expansion of the Indian iron and steel industry is a most important one, and may now be considered briefly.

The output of coal in India is steadily increasing, having risen from about 5 million tons per annum twenty years ago to over 20 million tons to-day. The total production in 1919 amounted to 22,628,000 tons, without reckoning the amount taken by the miners for their own use. Of this total, the Jherria and Raniganj fields produced 53·68 and 30·12% respectively, and the smaller Gondwana coalfields of Bihar and Orissa a further 8·56%.

In 1918 the Government of India, in view of the large avoidable waste of coal known to occur on the Raniganj and Jherria fields, engaged Mr. Treharne Rees to visit them and advise on the best methods of securing greater economy in the production and consumption of coal. Mr. Rees' report was submitted in August, 1919, and his principal recommendations include more efficient methods of coal extraction, the more economic use of power and more general employment of electricity, the improvement of methods of coke-making, the introduction of coal mixing, the more extended employment of screening, the possibilities of briquette manufacture, etc.

In January, 1920, the Government of India appointed a committee to consider Mr. Rees' report. It included representatives of the royalty owners, mining associations, firms engaged in mining, the Director of the Geological Survey of India, the Chief Inspector of Mines, and the Mining Engineer to the Railway Board. This committee toured the coalfields, examined numerous witnesses, and published a lengthy report in June, 1920.

In dealing with the question of coke production the committee show that only very approximate figures are available of the higher grade of coking coal reserves. The Raniganj coalfield alone contains over twenty thousand million tons of coal of all kinds, but most of this is inferior and only 518 million tons of first-class coal are estimated to exist. The addition of the Jherria reserves of the best coal brings the total up to nearly a thousand million tons. To the west of Jherria the Bokaro field is said to contain over six hundred million tons of coking coal, and it is possible that further reserves will be found in the untouched Karanpura fields still further to the west. Apart from these the only other coking coal known to occur in any quantity in India is that of Assam, the high sulphur content of which, however, makes it unfit for metallurgical purposes. The committee concluded that as far as is known at present, India will be dependent for metallurgical coke on the fields of the Damuda valley, and that although the total amount of coal they contain is undoubtedly very large, the quantity available for coke manufacture is strictly limited. Unless the resources are conserved and the use of the coal of lower grade substituted, wherever possible, for that of the better coking qualities, India may be faced at no very distant date with the loss of her metallurgical industries for want of coke. If the present rate of increase is maintained and an opportunist policy persisted in, the known reserves of two thousand million tons of

high-grade coking coals would be extracted in forty years.

Having come to this conclusion the committee made a number of recommendations to the Government of India, which still has them under consideration. These included the formation of a new Government Department and a Board as controlling authorities with legal powers designed to ensure conservation and economic extraction of coal.

It is necessary to point out that the mining engineer of the Railway Board submitted a minority report in which he stated his own personal belief that in the recently proved portions of the Jherria and Raniganj fields and in the Bokaro and Karanpura fields there are at least 300 years supply of good quality coal available.

It will be seen that the authorities are well aware of the position, and in the writer's opinion there is no need to fear that the growth of the Indian iron and steel industry is likely to be checked by the lack of metallurgical coke. Apart from the question of conservation, there are possibilities of extensions to known reserves of high-class coal in the undeveloped fields and to the results of research in the mixing, washing, and flotation of the poorer qualities.

The results of recent investigations in the United Kingdom on froth flotation as applied to the washing of industrial coal are of peculiar interest to India, as they have demonstrated that metallurgical fuels of a high degree of purity can be made from coals possessing a high ash content.

Conclusions.—According to Mr. C. P. Perin : " Since the beginning of the war prospecting parties have been continuously in the field working in a quadrangle 400 miles east and west by 200 miles north and south, beginning at Calcutta as the north-east corner. After investigations by some twenty prospectors, engineers of experience, and geologists connected with the different companies, there is now estimated to be about 20,000 million tons of high-grade iron ore within a maximum distance of the fuel of 500 miles and an average distance of 120 to 130 miles."

It will thus be seen that India possesses sufficient high-grade iron ores to supply an iron and steel industry of the first magnitude, and the rapid developments which are taking place show that this fact is fully appreciated by capitalists. The day would not seem to be far distant when India will be self-supporting as regards iron and steel and probably exporting pig iron to outside markets, for in the opinion of those best able to judge it can be produced comparatively cheaply, owing to the low assembly costs consequent on the close proximity of raw materials and the cheap rates of freight.

THE DIP COMPASS

By HENRY LOUIS, M.A., D.Sc., A.R.S.M., M.Inst.C.E., etc.,
Professor of Mining, Armstrong College, Newcastle-on-Tyne.

Methods of magnetic surveying are employed for locating such ore deposits as distinctly affect an ordinary magnetic needle ; such are mineral deposits that consist, or, at any rate, contain a large proportion, of either magnetite or pyrrhotite ; the former occur extensively in Scandinavia, Canada, and the Northern United States, as well as less abundantly in other places, while the best-known example of the latter is to be found in the important copper-nickel deposits of Sudbury, where these magnetic methods have, in fact, rendered excellent service. Comparatively recently attempts have been made to extend the principles involved to the location of ore-bodies of relatively low magnetic permeability, such as beds of ordinary ironstone. The method was elaborated by Mr. G. W. Walker under the auspices of the Iron Ore Committee of the Conjoint Board of Scientific Societies, of which I was Chairman, and a full report will be found in the *Philosophical Transactions of the Royal Society*, series A, vol. ccxix (1919), page 73. This method, however, requires elaborate and delicate instruments, and its consideration is beyond the scope of the present article, which refers exclusively to the methods as above defined. Owing to the fact that so many of the Swedish ore deposits carry large proportions of magnetite, these methods have originated and have been mainly worked out in Sweden. The earliest form of instrument appears to have been the Swedish so-called miner's compass, the invention of which is ascribed to Daniel Tilas, who died in 1672. As will be seen from Fig. 1, it consists of a cylindrical brass box, usually $1\frac{1}{2}$ to 2 in. in diameter, and of about the same depth, with a domed

glass cover. In the centre of the box there is a long steel pointed pin, on which revolves a cap, to which a magnetic needle is pivoted, so that this needle is free to move in both a horizontal and a vertical plane. There are no graduations, but a line is drawn round the inside of the box, which indicates the normal level of the north-seeking end of the needle when subject only to the magnetic influence of the earth. If this instrument is taken to any place where there is any magnetic influence other than that normally due to the earth, the north end of the needle will come to rest either above or below the marked line, and from its position an experienced man can tell whether magnetic deposits of any importance are likely to exist or not below the spot that is thus tested. It will be noted that the appliance is a crude one, but its indications are quite useful to a skilled observer.

Another form was introduced into the United States about 1866, which is generally spoken of as the American dip compass (see Fig. 2). It consists of a shallow brass box, 3 to 4½ in. in diameter, and ½ to ¾ in. deep, in which a magnetic needle is suspended on a horizontal axis so as to be capable of moving in a vertical plane only. The flat sides of the box are made of glass, and it contains a graduated arc so that the amount of dip can be read off. It is made by Messrs. W. & L. E. Gurley, of Troy, New York, and other American makers, and has also been copied by instrument makers in this country. In use it is placed horizontally and turned until the needle points to the zero of the graduation, and is then turned up into a vertical position so that the needle swings in the plane of the local magnetic meridian, when the amount of dip can be read off from the graduations. About 1898 I introduced an improved form in which I attempted to combine the advantages of the American and Swedish instruments; this I described fully in 1899 (see *Journal of the Iron and Steel Institute*, 1899, i, p. 80). It consists of a box like the American compass, only deeper, being 3 in. in diameter and 1½ in. deep, with glass sides. The needle is suspended as in the Swedish instrument, and behind it a semicircular arc is pivoted concentrically with the horizontal axis of the needle, so that the arc always hangs with its zero line horizontal. By turning the box until the needle swings freely about the vertical suspension it sets itself in the local magnetic meridian, and the amount of dip can be read off with considerable accuracy. The instrument is made by Mr. F. Robson, of Newcastle-on-Tyne, and I was able to do some good work with it. I have, however, abandoned it entirely for the form which I propose to describe presently. It had two drawbacks: the delicate suspensions were too apt to become deranged with work in the field, but above all it shared with all the instruments above described the serious drawback that it indicated dips in the plane of the local magnetic meridian, the objections to which method will be pointed out in the sequel.

Meanwhile, between 1870 and about 1880, two Swedish instruments, the Thalen magnetometer and the Tiberg inclinator, had been devised; they were subsequently combined in one instrument, which is practically the only instrument used at all extensively in Sweden to-day, and which is known as the Thalen-Tiberg magnetometer. This is used for making complete magnetic surveys of the area in which there are reasons for supposing that magnetic minerals occur; by this means curves of horizontal and vertical intensity can be plotted, from which the position of the ore deposit can be deduced. For a full description of these methods, the reader may be referred to a small work on the subject by Eugene Haanel, "On the Location and Examination of Magnetic Ore Deposits by Magneto-metric Measurements," published by the Canadian Department of Mines in 1904, which is entirely based upon the well-known work of Th. Dahlblom published at Falun in 1898. Without denying that this method may at times give information of the highest importance, my own experience has been that the results from an economic standpoint are not always reliable. Moreover, it is a somewhat slow and laborious method, and I have for some time past come to the definite conclusion that the results obtainable by it are not commensurate with the cost and labour involved in obtaining them. I have, therefore, reverted to the simple reading of dip angles as in the American dip compass, but have adopted the form of needle used in the Swedish magnetometer, which is intended to be read in a plane at right angles to the magnetic meridian. The dip compass thus designed, which I have used very successfully for a good many years, is now being put on the market by Messrs. T. Cooke & Sons, Ltd., York.

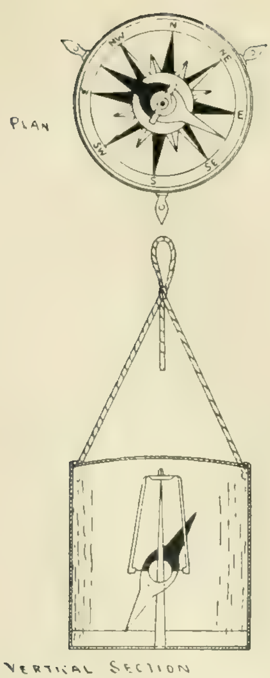

FIG. 1.

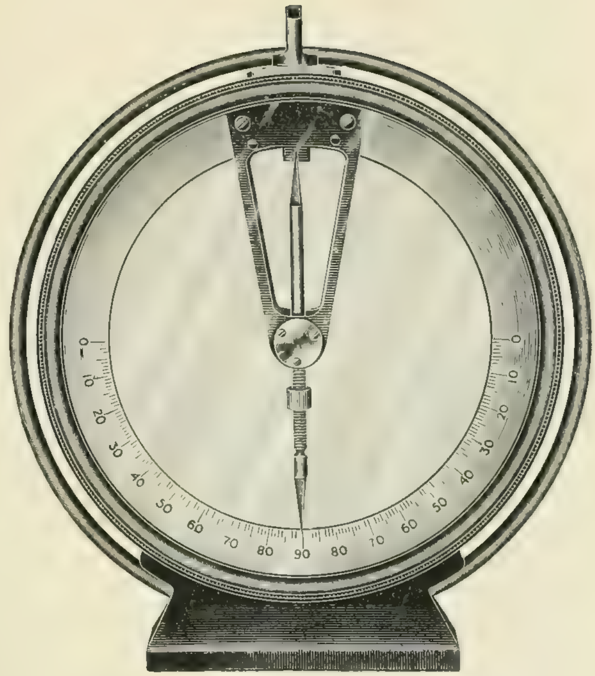

FIG. 3.

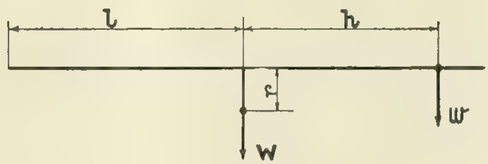

FIG. 4.

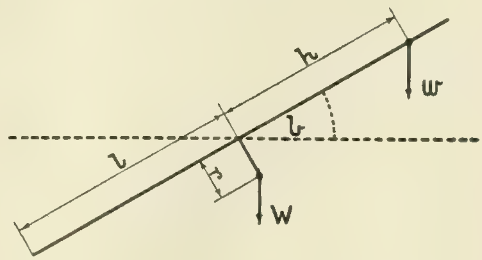

FIG. 5.

FIG. 2.

As shown in Fig. 3, it consists of a brass box, some 4 in. in diameter by about $\frac{3}{4}$ in. deep, the sides being made of glass, or better still, of transparent celluloid. It is suspended by a gimbal attachment, so that when held freely it hangs so that the line adjoining the zeros of graduation is truly horizontal; the base also allows it to be set on any level surface when more accurate observations

are desired. In the field I often use a light hand camera tripod for this purpose. The needle is suspended in carefully centred jewels, and it is necessary that much care and close attention should be bestowed upon the horizontal axis, so that the suspension may be highly accurate and work with the minimum of friction. The needle has a screw thread cut on one end (usually the south-seeking end), and on this a counterpoise, in the form of a small nut, moves smoothly but stiffly, so that the needle may be accurately adjusted in a truly horizontal position. Below the centre of the needle is a short pin of hard brass, also with a fine screw thread cut on it, and a little milled nut travels on this, so that the centre of gravity of the system can be brought to any desired point below the centre of suspension. By placing it flat and turning the box the needle can be brought into coincidence with the 90° mark of the graduation ; on now turning the instrument into a vertical position, the needle will be constrained to move in a vertical plane at right angles to the local magnetic meridian.

In order to understand the principles involved, it is necessary to recall briefly some of the elementary facts concerning the magnetism of the earth. If a magnetized steel needle be suspended quite freely from its centre of gravity, it will set tangentially to the lines of force in the magnetic field of the earth at that point, or, in other words, the magnetic force of the earth will be acting along the axis of the needle. It is convenient to resolve this force into its horizontal and vertical components ; in order to give some idea of the forces involved it may be mentioned that in this country the horizontal intensity (H) is about 0·185 C.G.S. units, and the vertical intensity (V) about 0·435 C.G.S. units. It need hardly be said that these values are continually changing, though the change is a relatively slow one.

Assuming that a magnetic needle be suspended from its centre of gravity in the plane of the magnetic meridian at a spot where it is subject only to the magnetic influence of the earth, it will then have a definite dip or inclination ; let the angle of inclination measured from the horizontal be I ; now let the needle be placed in another plane making an angle a with the plane of the magnetic meridian, and let its dip be i. Then $\tan I = \frac{V}{H}$; in the second position the horizontal intensity becomes $H \cos a$, hence $\tan i = \frac{V}{H \cos a} = \frac{\tan I}{\cos a}$. Accordingly, when a is 90°, or the needle is in a plane at right-angles to the magnetic meridian, i becomes 90°, and is then a maximum. Furthermore, it is evident that in this position H has no effect upon the inclination of the needle, and its action is therefore eliminated. If a needle be brought to a spot where it is subject to a magnetic influence other than that of the earth, as, for instance, if it is brought near a mass of magnetite, if the needle is in the plane of the local magnetic meridian, both the horizontal and vertical components of the field due to the mass of magnetite as well as those due to the field of the earth will affect the needle. Conceivably the components of the former might be in the same ratio as those of the latter, and in this case the dip of the needle would not be altered, and the presence of the deposit would not be detected ; even if this were to occur, it would only be in one position, and the presence of the deposit would be detected by an alteration in the dip of the needle as soon as a second observation was made. Moreover, in the vast majority of cases the vertical component due to a mineral deposit below the surface of the earth is much greater than the horizontal component, and therefore the dip of the needle is in most cases affected. It is, however, obvious that since the dip depends upon a number of variable conditions, the relation between the angle of dip and the magnitude of the magnetic forces involved cannot be stated in general terms, but must be determined independently for each set of conditions ; it can only be said quite generally that the extent to which the dip is affected will as a rule be greater, the greater the magnetic forces involved. In other words, observations with the magnetic needle in the magnetic meridian have a qualitative but not a quantitative value. It is on this account that I now always work with the magnetic needle at right angles to the plane of the meridian when quantitative measurements can be obtained, as will appear from the following considerations.

In Fig. 4 w is a counterpoise sliding along the needle to counterbalance the vertical component of the earth's magnetic force when the needle is in a plane at right angles to the magnetic meridian ; it is set at a distance h from the centre of the needle, and W is a small weight placed at a distance r

from the centre of suspension of the needle. Let the distance between the poles of the magnetic needle be $2l$ and let m be the magnet pole strength. Then $wh = mV2l$.

Now let the needle be brought into a field whose strength vertically is $V + dV$, where dV represents the change in the vertical component of the field, and let the needle now come to rest in an inclined position making an angle of inclination b to the horizontal (Fig. 5). The equation of moments is now $w\ h \cos b + W\ r \sin b = m\ V2l \cos b + m\ (dV)\ 2l \cos b$, whence $\tan b = \frac{m\ (dV)\ 2l}{Wr}$ and $dV = \frac{Wr \tan b}{m\ 2l}$.

Thus the change in the field is proportionate to the tangent of the angle of inclination; for small angles no serious error will be committed if the change in the field is taken as proportional to the angle itself. Furthermore, it will be seen that the angle becomes greater as r is diminished, so that the needle can be made very sensitive, and will indicate bigger angles of inclination for the same change in the magnetic field if the small weight W is brought closer to the point of suspension of the needle. By the construction of the instrument m, l, and W are constant.

In order to make a series of observations, the needle must first of all be adjusted at a place near the field to be investigated, where there is no magnetic attraction other than that of the earth itself. The compass is now placed flat and turned until the south end of the needle coincides with the 90° graduation; it should be gently tapped to make sure that it is in the magnetic meridian. The compass box must now be turned into a vertical position when it will be in a plane at right angles to the magnetic meridian; one of the side cover glasses is now removed, and the counterpoise w is screwed to and fro until the needle is exactly horizontal. The cover glass is replaced, and the instrument is taken to the field to be examined. The same procedure is repeated; the instrument is held horizontally until the south end of the needle, moving freely, coincides with the 90° graduation mark. It is then turned into a vertical position and the inclination of the needle is noted; inclinations of the north end are usually given a + sign, and those of the south end a — sign. If the readings are too small or too large for convenience, these can be altered by moving the small weight W towards or from the point of support, but its position must not be again altered while a set of readings are being taken in a given field.

It will be noted from the above investigation that if the plane of the needle does not coincide exactly with the plane perpendicular to the magnetic meridian, a small deviation will produce no serious error. Seeing that $\cos 8° = 0{\cdot}99$, even if the plane of the needle is 8° out of the plane perpendicular to the meridian, the error in the tangent of the angle of inclination would only amount to 1%.

If desired, this dip compass can be used for setting out curves of equal vertical intensity, exactly as is done with the elaborate and expensive Swedish instrument, the method here recommended being at least as accurate and much more rapid, although it requires two observers. Instead of setting out a network of squares over the ground as is done in the Swedish method, I recommend that one observer use the dip compass, in conjunction with another who will plot the position of the first observer by surveying, preferably using a plane table. For this purpose I strongly recommend the use of the tacheometric plane table (see my paper on this subject in the *Transactions of the Institution of Civil Engineers*, vol. cciii, 1917, page 359). This method will be found satisfactory and expeditious, and can, of course, be combined with the survey of the area under examination.

This form of dip compass also renders important services underground when working deposits of magnetite or pyrrhotite. Assume that an approximately vertical lenticular mass of such ore has been opened up by means of an adit which has penetrated into the ore-body; obviously if a dip compass be taken into the adit it will be affected by the ore both above and below the adit; at the surface above the deposit the needle will probably show a well-marked dip; the dip will be less in the adit because the portion of the deposit above the adit will be drawing the needle upwards while the portion below the adit draws it downwards, and it is thus easy to determine whether the adit has cut the deposit above or below its centre, and even to form some idea of the depth to which the deposit is likely to extend. If the deposit is opened up at several different levels and such observations are made at each level, quite reliable conclusions as to the permanence in depth of the deposit can be drawn.

BOOK REVIEWS

A Geological Map of the World. By HENRY B. MILNER, M.A., F.G.S. On Mercator's Projection, one sheet 45 in. by 28 in. Price 25s. net. London: Edward Stanford, Ltd.

The primary object of this publication is the presentation in an easily accessible form of an accurate geological map of the world, compiled from the most recent and authentic stratigraphical criteria available. For a long time the need has been felt for a general "index" map of this nature, which, while omitting detailed definition such as must necessarily be obtained from a study of original large scale maps of a particular region, depicts the broader outlines of the geology of the country whereof that region forms a part. Moreover, the co-ordination and correlation of the results of stratigraphical work by different geologists in contiguous countries is desirable in order that our geological knowledge of the continents of the world could be summarized as far as present data permitted. A comparison of this map with Marcou's well-known work published some fifty years ago shows at a glance the enormous amount of pioneer field-work carried out since that time, and if only as a tribute to the ability and perseverance of those engaged in this research, the map was most certainly justified.

Geological investigation, whether carried out by national survey or by private individuals, must of necessity be limited in scope; its very nature demands the careful observation of comparatively small areas in great detail if it is to be of ultimate scientific or economic value; hence there is bound to be a natural tendency towards the accumulation of a vast amount of local geological data, which, by reason of its magnitude, may and often does unconsciously mask the larger and fundamentally more important geological issues. This wider view of the potentiality of such work can only be appreciated by the co-ordination of the more far-reaching elements of knowledge locally amassed, and a geological map of the world would seem to be the best medium for utilizing such knowledge to the fullest extent in illustrating the fundamental geology and tectonics of the earth's crust. Particularly in the study of such authors as Suess or de Lapparent is a map of this description desirable for constant reference, to promote cohesion of thought and to facilitate the grasp of doctrines which they seek to establish.

The map is drawn on Mercator's projection, and its size is approximately 45 in. by 28 in.; latitude and longitude are clearly defined to enable precise localities to be fixed, but no place-names whatever are printed on the map. Inclusion of such names would have undoubtedly complicated the intricate geological detail shown in many cases, and would have made the defining lines between different geological systems difficult to follow, especially in such countries as Europe and North America; actually this omission of place-names is of little consequence to those to whom the map will make its greatest appeal, since it may be safely presumed that their geographical knowledge is comprehensive enough to embrace such names as might possibly have been incorporated in a map of this size. In any case its study in conjunction with topographical maps of the countries represented is advocated by the author. The colours used are as far as possible uniform with the standard international colour-scheme adopted in publications of this nature, though certain additional conventions have been introduced to depict undifferentiated geological systems such as the Trias-Jurassic, as in Australia, New Zealand, South Africa, etc. In the pamphlet issued with the map, the author explains the reasons for the blank spaces occurring, and for the omission of certain geological data resulting from the survey of some of the better known inland watercourses of Central South America, Central Africa, and Siberia; in the former case either no authentic stratigraphical records exist, or if they do, their comparatively sketchy character inhibits their inclusion; in the latter instance the reduction to the varying scale necessitated by the size and projection of the map of such results as are published is thereby rendered impracticable, and no possible scientific value would accrue to the mere insertion of a few short sinuous lines bordered by hazy, narrow bands of colour, representing the geology of one or two little known rivers. The author's contention that such blank spaces are better left until more areal work is carried out in those countries (when published results can easily be added by the intelligent reader) is certainly sound, and more in keeping with the character and purpose of this publication as a whole.

The specific utility of a map of this description is twofold: scientific and economic. Scientifically its uses are obvious in all branches of academic instruction; for the student it forms a basis for a broad and intensive study of the geology of the world; for the professional geologist it constitutes a ready means of reference to regional geology otherwise only accessible at a great deal of trouble and bibliographical research. Economically it portrays to the capable observer those essential geological factors cognate to any enterprise for the development of the natural mineral wealth of the world, since the dominant igneous or sedimentary nature of a particular region can be at once ascertained, the more important coalfields located, and the probable petroliferous regions suggested from a close study of structure and disposition of likely formations such as those of Tertiary age.

Copper Refining. By LAWRENCE ADDICKS. Cloth, octavo, 206 pages, illustrated. Price 17s. net. New York and London: The McGraw-Hill Book Co.

The book, to a large extent, contains the results of Mr. Addicks' personal experience in this branch of metallurgy, and comprises a series of articles each dealing with one of the problems of copper refining. These articles appeared originally in *Chemical and Metallurgical Engineering*, and have now been embodied in a volume, seeing that the literature dealing with the principles of operation of electrolytic copper refining is limited. The work is in a way unique, inasmuch as it deals largely with possible losses and errors in the various stages of copper refining, while the economic side of the subject is carefully considered throughout.

It contains 13 chapters under the following headings: I, Metal Losses; II, Metals in Process; III, Tank Resistance; IV, Current Density; V, Current Efficiency; VI, Impurities; VII, By-products; VIII, Furnace Refining; IX, The Requirements of Refined Copper; X, Copper from Secondary Material; XI, The Power Problem; XII, Elements of Design; XIII, Application to Other Fields.

The salient points in connexion with the sampling of the various refinery materials are clearly indicated. This is of the first importance in any investigation of metal loss, as the values shown by the sample have to be paid for whether they exist or not. Some assaying precautions are given, especially in connexion with bullion, and the author wisely points out that "mismanagement in the laboratory may easily affect the apparent or financial metal losses". Metal losses, such as those in slags, stacks, and processes, are dealt with; in the last-mentioned there are included such losses as: (1) silver and gold in outgoing copper, (2) silver in outgoing gold, (3) gold in outgoing silver, and (4) values such as selenium, platinum, etc., lost in by-products.

A careful survey is taken of the metals undergoing electrolytic treatment, and the means are indicated of checking the position at each stage of the process. Since this class of refining takes considerably longer than fire processes (which are as a rule not so satisfactory technically), there are large amounts of valuable metals locked up and these impose heavy interest charges. It is shown that an increase of current density is closely related to plant investment and the quantities of metals continually under treatment, while the power required increases nearly as the square of the current density. A detailed study is made of the possibilities of improving tank resistance, since, in practice, a number of resistances and counter electromotive forces have to be overcome. It is also shown that the current density is the factor of an electrolytic process which is more important than all others in the design and operation of a plant, as so many items depend upon it in order to obtain the best return for the capital invested.

The question of current efficiency is discussed, and the author shows that, although nine sources of loss are always present, yet they can all be kept low. In a badly running plant the current efficiency may be as low as 60%; he regards 85% as poor; good balanced operations will give 92%; while with efficiency regardless of expense 99% may be obtained.

About 20 pages are devoted to impurities, which are placed under six main headings: (1) Sources; (2) Exits; (3) Distribution; (4) Chemical requirements of refined copper; (5) Recovery of soluble impurities from the electrolyte; and (6) Recovery of insoluble impurities from anode slimes. Very useful information is given in connexion with the purification of the electrolyte, while the various elements, usually associated with copper, are discussed. The means by which the anode slimes are worked up into marketable materials are given, and the by-products

are divided into three main classes: (1) Those which are readily marketable in any quantity (gold, silver, platinum, palladium, lead, nickel, and antimony); (2) Those which have a limited and therefore a widely fluctuating market (bismuth, arsenic, cobalt, selenium); and (3) Materials which have no market at the present time (tellurium).

The requirements for a slime process are stated, and it is pointed out that, as the material usually runs 35 or 40% silver and ½% of gold, every by-product must be re-treated for values contained. As the slime is a valuable material, it is essential that the bulk of the gold and silver should be recovered as rapidly as possible. This involves three main steps: (1) The production of a nearly copper-free slime; (2) Smelting the slime from No. 1 to doré bullion; and (3) Parting the metal obtained. A considerable amount of attention is given to these stages, and the author shows, by means of flow-sheets, the advance which has been made in the treatment of copper-anode slimes during the past 20 years. This difficult branch of the metallurgy of a copper refinery is treated in a very lucid manner.

About 18 pages are devoted to Furnace Refining, and the various stages of the process are described: Charging, melting, flapping, skimming, coking, poling, and pouring. The section on pouring is of special interest, as development is traced from the Welsh practice of using a ladle holding some 15 or 20 lb. of copper to the special twin ladle with which casting can be conducted at the rate of over 100,000 lb. an hour. Some attention is given to the preparation of moulds, the formation and retreatment of slags, and the thermal efficiency of the refining furnace. As regards future developments, it is pointed out that, during 20 years, the furnaces have changed from 20 to 250 tons per 24 hours capacity, and larger furnaces could easily be built were there any justification for it. The hearth is now constructed of magnesite brick for corrosive charges, while the walls, verb, and sometimes the entire roof are now built of chrome or magnesite brick.

Although the bulk of the world's copper is refined electrolytically, yet two reverberatory treatments are retained: the anode and the refining furnaces. The first operation is satisfactory, but the latter, instead of being a simple melting, really becomes a complete refining; the author mentions the possibilities of the electric furnace and of continuous melting, but he considers the latter more attractive.

The requirements of refined copper are considered under the headings of conductivity, pitch, ductility, castings, and dimensions, over about 17 pages. Much useful information is given which is illustrated by means of graphs and references to original papers in the Transactions of the American Institute of Mining Engineers. The production of copper and incidental metals from secondary materials is often a paying proposition, and this book contains considerable guidance respecting the treatment of this class of material, which may consist of junk, mill products, metallurgical products, and refinery by-products.

The power problem of an electrolytic copper refinery is considered merely from the general requirements and limitations of the problem as a whole. There is, of course, available heat from the reverberatories for the generation of steam, and, if the running is sufficiently uniform, it may not be necessary to use power generated in other ways, such as by a hydro-electric or gas plant. The author places the current density at 18 amperes per sq. ft. in average practice and the temperature of the electrolyte at 130° F.; under these circumstances the power consumption will approximate 350 kilowatt-hours per ton of copper deposited. With a refinery having a capacity of 100,000 tons a year, a power capacity of 4,000 kw. should be available.

Under the heading "Elements of Design" some space is given to the location of plants. The author states that the nations of Europe, since the war, have developed a desire to control key industries complete within their borders, and this may bring about the building of new refineries. Important points in connexion with the design of the power-house, tank-house, and the furnaces are reviewed, while a certain amount of attention is given to silver-refining and to purification. Two main principles should be kept in mind in operating the plant: (1) All the impurities should be removed as far as possible at the anode furnace; (2) Operating conditions should be brought to the highest limits of uniformity.

The book is concluded with a chapter on the application of electrolytic refining to other fields, and the cases of the precious metals, zinc, and lead are specially considered. The electrolytic process for lead is particularly interesting, as it has to com-

pete with the efficient Parkes process, and apparently the only economic advantage it possesses is that the bismuth present can be saved.

Dr. Percy stated that metallurgy is the art of extracting metals from their ores and adapting them to various purposes of manufacture *with profit*. It has evidently been the object of the author to indicate those points, often small ones, where savings and improvements can be effected, so that the refinery may be worked under the best conditions for economical efficiency and a suitable return obtained for the capital expended.

The work contains a number of flow-sheets, diagrams of processes, and other useful data ; there are many suggestions for future developments and consequently much food for reflection. We strongly recommend this volume to all who are interested in the metallurgy of copper.

W. H. MERRETT.

A Text Book of Assaying. By C. and J. J. BERINGER. Fifteenth edition, revised by H. R. BERINGER. Cloth, octavo, 480 pages. Price 12s. 6d. net. London : Charles Griffin & Co., Ltd.

Those whose business it is to watch the development and progress of assaying in its various branches cannot have failed to notice the comparative scarcity of good books on the subject by English authors. America, with its huge mineral resources and constantly varying metallurgical problems, affords ample scope for new methods and modifications of existing methods to meet local conditions. Consequently it is not surprising to find that the majority of present-day books on assaying or metallurgical analysis are American in their origin or inspiration. It is all the more a matter for congratulation, therefore, that the work under consideration, well-known to mining men the world over, should reach a fifteenth edition.

The edition under review preserves the familiar form and arrangement of previous editions, and contains new matter relative to the assays of tin, tungsten, copper, arsenic, zinc, and manganese. The section on tin contains the assay method associated with the name of the late J. J. Beringer, and, with the account of Hutchin's lime method and of the Pearce-Low assay, constitutes an excellent survey of the present position of tin assaying. A valuable addition to this section is an appendix, containing the assay methods of the Eastern Smelting Company, Penang. The section on tungsten includes the latest work of Hutchin on the use of cinchonine. Other additional features are the well-known aluminium and hypo separations for copper, the Volhard assay for manganese, and Low's method for zinc.

It would perhaps be idle to criticize a book which has so firmly established itself as a standard book of reference. We confess to some surprise, however, that no reference is made either to any bismuthate method for manganese, or to the glyoxime method for nickel. It may be put forward that the cost of these reagents (a first cost only in the case of glyoxime, since it is readily recoverable) is a bar to their use on mines or works in remote districts. Nevertheless, in a book used so largely by students, we think they deserve at least a brief mention. It is presumably chiefly as an exercise for students that the dry assay of nickel and cobalt is given prominence.

Under the heading of chromium a gravimetric method is described for the determination of this element in steel. Standing alone as this method does, it is apt to create the impression that no other method exists for this purpose, whereas there are obviously several good and much used volumetric methods.

Some of these matters are inconsistencies rather than defects, and, containing as it does few methods that are not chemically sound, the book should continue to hold its own as a reference book for those connected with mines and for technical chemists in general.

B. DRINKWATER.

Compressed Air Plant. By ROBERT PEELE. Fourth edition, cloth, octavo, 506 pages, illustrated. Price 25s. net. New York : John Wiley & Sons ; London : Chapman & Hall.

The extension of the use of compressed air during the last decade or two and the certainty of a still greater recognition of its advantages in the near future make the subject one of considerable importance to engineers, whether civil, mechanical, or mining. How wide the field of application of this medium of power transmission has become may be judged by an enumeration of some of its employments : elevating, transferring, and stirring liquids in chemical works, atomizing liquids, spraying paint

and cement, blast-furnaces, glass-blowing, caisson and other subaqueous work, railway switching and signalling, air brakes, riveting and other pneumatic tools, sand-blast, refrigerating, haulage locomotives, hoists, flotation machines, coal-cutters, and rock-drills. In view of the difficulty of dealing with the subject in all its ramifications within a reasonable compass, the author, who is the professor of mining in the School of Mines of Columbia University, and the editor of the well-known and valuable *Mining Engineers' Handbook*, decided to confine himself mainly to the consideration of the production, transmission, and use of compressed air in mining.

The scope of the work is well indicated by the titles of the twenty-seven chapters into which it is divided: Introduction, structure and operation of compressors, the compression of air, wet compressors, dry compressors, compound or stage compressors, air-inlet valves, discharge or delivery valves, mechanically controlled valves and valve motions, performance of air compressors, air receivers, speed and pressure regulators, air compression at altitudes above sea-level, explosions in compressors and receivers, air compression by direct action of falling water, conveyance of compressed air in pipes, compressed-air engines, freezing of moisture deposited from compressed air, re-heating compressed air, compressed-air rock-drills, hammer drills, coal-cutting machinery, channelling machines, operation of mine pumps by compressed air, pumping by the direct action of compressed air, compressed-air haulage, measurement of air consumption.

The space allotted to the turbo-compressor will be considered by some hardly commensurate with the increasing attention which is being devoted to its development. It is true that below a capacity of 5,000 cu. ft. of free air compressed per minute, it is not the most economical type, but above that level of output it successfully challenges the highest grade reciprocating compressors. Entire absence of valves and reciprocating parts, compactness, freedom from vibration, suitability for direct high-speed electric or turbine drive, ower initial and maintenance cost, high capacity in proportion to weight and floor space occupied, and elimination of danger of explosions in air receivers and pipe lines due to the comparative absence of oil, make it an ideal machine where a large output is required. Turbo-compressors are now made in standard sizes with a capacity of from 5,000 to 50,000 cu. ft. of free air per minute to a pressure of 130 lb. or more per sq. in. The number of impellers in series may be as many as 30, the speed 3,000 to 5,000 revs. per min., and the horse-power as much as 13,000. The increment of the pressure per impeller varies from 2 to 8 lb. per sq. in., 4 or 5 lb. being common practice. About 20 impellers in series are required to produce a final pressure of 100 lb. per sq. in. at 4,000 revs. per min.

An interesting description is given of some installations of the hydraulic system of air compression developed by C. H. Taylor. Air is introduced into a column of water, and is compressed as it and the water fall together to the bottom of a shaft, where the air is separated and collected. The first cost is not disproportionately heavy for large outputs, while the efficiency is good, and maintenance and running costs very low. A peculiar feature attending this method of compression is the lowering of the percentage volume of oxygen in the air from 21% to 18%, with a corresponding increase in the nitrogen content. In some mines this has prevented the use of candles for lighting.

Much useful information is given concerning the air-lift. Since 1888, when Dr. Julius Pohlé drew attention to the possibilities of this device, its progress has been steady, if slow. It is specially applicable to the drainage of shallow mines and as an aid in unwatering old and flooded mines. It possesses the great advantage that, once installed, it can be operated entirely from the surface; no pumpmen are needed in the mine, and if the power fails and the water rises no pumps are lost. The efficiency is from 20 to 40%. Until recently it was thought that a submergence of 50% was necessary to obtain reasonable results, but an installation in a Mexican mine has shown that an efficiency of 30% is obtainable with a lift of over 1,000 ft. and a submergence of only 20%. The principles of the air-lift are as yet imperfectly understood, and its design is consequently faulty; but even in its present immature stage the work it is doing holds out considerable promise of its becoming a valuable auxiliary in mine drainage.

It is to the chapters on rock-drills that the mining engineer, remembering young and strenuous days with them in the mine and maturer days in the office wondering which sort to buy, will instinctively turn. J. J. Couch in 1849 began, and Sommeiller in 1861, Burleigh in 1866, Simon Ingersoll

in 1871, and J. George Leyner in 1897, continued the rock-drill's slow, irresistible development. The old, two-man, reciprocating drill, a wonder in its day, is almost a thing of the past. One-man reciprocating and hammer drills are the machines of the present. Jackhammers for sinking, reciprocating, cradle hammer, and telescopic air feed hammer for driving and stoping; and telescopic air feed hammer for rising, are popular for the duties indicated. The two main types are used to the extent of about 30% reciprocating and 70% hammer, the latter steadily gaining. The design of the newest hammer drills aims at: light weight and small size, automatic rotation, automatic feed, automatic lubrication, drilling speed, water feed, air economy, strength and simplicity, ease of adjustment and repair, and ability to stand rough usage. The perfect drill of the future is likely to approximate to neither of the main types, but to assume the form of a non-vibratory, comparatively noiseless, rotary borer. With the ever-growing command over materials and increasing knowledge of their uses, it is not stretching imagination too far to suppose that some means commercially applicable to the drilling of hard rock more quietly, efficiently, and cheaply than present methods seem ever likely to allow will before long be discovered.

Two very interesting designs of hammer drills embodying automatic rotation now on the market are the Waugh Turbo and the Holman Auto. The former is a cradle machine equipped at the chuck end with an air turbine, which enables the drill steel to be revolved quite independently of the piston hammer. The latter is a telescopic air-feed machine, fitted at the rear end of the extension with an independent reciprocating air motor, which by means of a splined rod oscillates the drill steel. Both of these machines mark a distinct advance in drill manufacture.

The first edition of this book appeared in 1908, and met with gratifying success. The issue of three later editions, each one showing careful revision and embodying useful additions, in the succeeding twelve years has shown that the author is alive to the need of keeping its contents abreast of the times, and that a large circle of appreciative readers are at one with him. Although the general excellence of the treatise precludes much in the way of criticism, a few comments may be offered, in the hope of benefiting future editions. The types of American rock-drills illustrated and described represent the best American practice, but a similar verdict hardly applies to the English machines depicted. No reference is made to the now fairly common adjunct to the large modern mine plant—the air operated drill sharpener. Liquid air would seem to deserve mention in view of its manufacture through the compression and expansion of air, its use in mine rescue apparatus, and its employment as a blasting agent. An amplification of the cost data of plant and operation would be helpful to those who have to inspect the business aspect of the subject; and a bibliography would also be a useful addition.

The attractiveness of the work is enhanced by good quality paper and printing and 258 excellent illustrations, while interest is secured by a scholarly presentation and a blending of theory and empiricism in agreeable proportions.

ALEX. RICHARDSON.

Electrolytic Deposition and Hydrometallurgy of Zinc. By OLIVER C. RALSTON. Cloth, octavo, 201 pages, illustrated. Price 18s. net. New York and London: McGraw-Hill Book Company.

The publication of this book on a specialized subject such as the electrolytic deposition and hydrometallurgy of zinc, so shortly after the proved commercial success of the processes to a study of which it is largely devoted, is an indication of the enormous demand existing at the present time for specialized technical books. The author has undoubtedly done a service to metallurgists in putting on record so promptly many details of the operations involved, and has run the risk of omitting much matter which might have been included had publication been delayed a little longer. Although published only this year, two important papers have already been read since its publication, one describing the electrolytic zinc plant of the Anaconda Company at Great Falls, by F. Laist and his associates, read before the American Institute of Mining and Metallurgical Engineers in February, and the second, read before the Faraday Society by S. Field, describing work done in this country. Both these papers contain a considerable amount of information which might with advantage have been incorporated in the book, and a

knowledge of the matter in these papers makes the reading of the book a little disappointing.

The book contains an excellent history of zinc hydrometallurgy, from which it appears that ever since 1880 serious attempts have been made to place these processes on a commercial basis, but real success was not met with until 1915, when processes were worked out by the Consolidated Mining and Smelting Co. at Trail and by the Anaconda Copper Co. Each developed a simple process of roasting the ores, followed by leaching with dilute sulphuric acid, purification of the solution obtained, and electrolysis to obtain zinc cathodes and regenerate sulphuric acid at the anodes. The purification of the solution was the most important matter worked out, and after the realization of the necessity for this, and by the development of suitable methods and plant for its accomplishment, the electrolytic production of zinc became a commercial success. The roasting, leaching, and purification of zinc sulphate solutions receive attention, and the effect of the presence of the various impurities generally present is dealt with in detail. Cobalt has proved to be one of the most baffling impurities in zinc sulphate solutions, for minute quantities have powerful effects on the re-solution of the cathodes, 10 parts per million seriously impairing the deposition and 15 parts per million being fatal to the process. The work of Hansen, Laist, Elton, Caples, Frick, Hanley, Gepp, Stevens, Snow, Clevenger, and Field in connexion with the purification of solutions is described. The electrolysis of zinc sulphate solutions receives full attention and details of practice on various plants are given.

Although practically all the electrolytic zinc at present on the market is deposited from zinc sulphate solutions, the chloride solution is in use in a few places, and the processes which have been suggested from time to time for the production of the chloride from ores are described, including roasting with salt and chlorination with chlorine gas, chlorination with solutions of metal chlorides, and by-products such as calcium chloride and hydrochloric acid. The chloride of zinc solutions obtained by these processes have many applications in chemical industry, so that, apart from electrolytic treatment, the methods of purification are important and do not differ greatly from the methods used for sulphate solutions. For the electrolytic production of zinc, the chloride solution may be electrolysed as such, or evaporated to dryness and the resulting zinc chloride fused and electrolysed in the fused state. Only aqueous electrolysis is in commercial operation, although fused zinc chloride cells have been tested on a large scale by several different companies, and details as far as available are given of both methods.

To the electrolytic refining of impure zinc, galvanizer's hard dross, and zinc crusts from desilverizing works, one short chapter is devoted, in which most of the important experimental work on these lines is described.

A chapter is also devoted to hydrometallurgical methods used for the preparation of zinc compounds from ores, including ammoniacal leaching, bisulphite leaching, etc., and the manufacture of lithopone, zinc sulphate, and zinc chloride.

In the final chapter the economics of zinc hydrometallurgy are dealt with, and the author is correct in stating that a single chapter (of six pages only) will not suffice to adequately discuss the economics involved in choosing a wet method of zinc extraction in place of the standard fuel smelting process or the electric smelting process. The author concludes that the present state of advancement in the art makes it economical to use electrolytic recovery of zinc only on the more complex sulphide ores, although its application to the treatment of pure ores might have been attractive were it not for the great surplus of smelter capacity in close proximity to such deposits as those of the Joplin district.

C. O. BANNISTER.

NEWS LETTERS

MELBOURNE

March 25.

MINING CONDITIONS IN AUSTRALIA.—Mr. M. A. Davidson, M.L.A., chairman of the Select Committee appointed by the New South Wales Government to inquire into the decline of metalliferous mining in the State, has issued an interim report based on the committee's inquiries in Armidale, Emmaville, and Tingah districts. The report refers to the fact that, unlike other industries, increase in the cost of production in the metalliferous mining industry cannot be passed on. For this reason it is urged that special support should be given the industry

by the State Government, which should fix the price of base metals commensurate with the cost of production, and hold the metals in reserve until the market value has revived. As an alternative, it is suggested that an advance on the amount of base metals produced should be made to companies which had not previously made large profits. The export embargo, imposed during the war, is deemed to be now unnecessary, and its immediate removal urged, while it is recommended that the State Government should take into immediate consideration the advisability of a modern plant established in a central position for the treatment of ores in Australia, instead of shipping them abroad. Greater encouragement of prospecting is advocated, by increasing the amount of financial aid and assisting in the establishment of treatment plants. A geological survey of the metalliferous areas of the State, it is urged, should be undertaken, as early as possible, and the geological survey staff increased to ensure its rapid completion. Light railways linking up with main lines and improved roads are stated to be an urgent necessity, while it is stated that the continually increasing freights, railways and otherwise—which increases cannot be passed on—have been a great factor in the closing down of some of the smaller and low-grade mines, and a general flat rate, greatly reduced, for ores, is recommended. The report concludes by stating that a proper system of organization is required, and asks : is it preferable to allow mines to close down and the employees to drift to the city and cause a big increase in the already huge amount that is being spent by the Government in relieving distress, or to place the amount of money into the industry, thereby reviving the production and eventually obtaining a refund of the money now being spent.

Last week-end the Select Committee took evidence in Broken Hill. The first witness was the mining warden, Mr. A. R. Perry, who has had experience in several parts of the State. He had, he said, noticed a great falling off in the number of prospectors, which he considered to be due to the unremunerative nature of the occupation. Broken Hill was a rich man's field, and the poor man had little chance. The prospector should be protected and encouraged to the uttermost. A small treatment plant would help prospectors considerably. Mr. W. Riechers, who had prospected in the district for six years, said that he worked for lead, zinc, and silver at the Allandale mine, where he erected a concentrating plant, capable of treating ten tons a shift. It had given good results, and the costs were very moderate. He would like to see a small concentration plant put by the Government near the railway for the benefit of prospectors. Its cost need be only about £3,000 or £3,500. It did not pay prospectors to send crude ore away, because of the heavy freight charges. Witness was interested in a mine at Thackaringa. He produced a general sample of zinc ore, which would assay about 61%. There was no market for the zinc, because of the Federal Government's ten years' contract with the British Government. The small men had no market. The Federal or State Government should find a market for the small producers.

Thomas Ham, underground manager at the Junction North mine, gave some interesting particulars about the tinfield at Euriowie. If there was a portable battery there, he said, much more work could be done, and the place could now carry, at the present price of metals, 150 to 200 men instead of being idle. He had worked at one mine at Euriowie 32 years ago, and he did not think that anyone had worked there since. There was good tin there. He had seen a lode from 10 ft. to 30 ft. wide. Witness did think that the Broken Hill mines could work at a profit at the present price of metals. From a show at White Cliffs, witness sent some ore to the Wallaroo smelters that showed 32% copper, but the smelting charges were 8s. a unit. There was also gold in the ore. The show was now lying idle ; he could not touch it, because of the low price of copper. He considered it absolutely essential, for the good of the industry, that prospectors should be helped. The Prospectors' Association favoured the creation of local prospecting boards, said this witness, and the increasing of the powers of the local wardens, to obviate the long delays caused through everything having to be done through Sydney. Witness did not believe that anything payable had been found outside the known line of lode for 25 years.

Early Ice Ages.—Discoveries of evidence of glaciation on igneous rocks of Carboniferous age have recently been made in the Maitland district, New South Wales, by Mr. W. R. Browne, a lecturer in the geological department of the Sydney University. Professor Sir Edgeworth David has discussed these discoveries at some length in popular language, and the substance of his remarks

is given herewith, without omission of the explanatory portions intended for the layman.

Prior to this discovery, surfaces of granite rock, grooved and striated by the movement of a glacier ice, have been described as occurring on the Kosciusko Plateau. These ancient glaciated pavements at Kosciusko were worn down and grooved by the ice at a period probably some 10,000 to 50,000 years ago. The special interest attaching to this new discovery is that it is evidence of a far older glaciation, dating back to some 250 millions of years ago. This period, known as the Carboniferous, somewhat antedates the epoch of the oldest coal measures in Australia, namely, the Greta coal measures of the Lower Hunter region. There is evidence that glacial conditions were prolonged at intervals for some time after the formation of the Greta coal measures had been completed, but just previous to the deposition of the Newcastle-Bulli-Lithgow coal measures with the underlying Tomago coal measures. Thus the Greta coal measures of New South Wales, in which the most productive collieries of the northern coalfields are at present situated, belong to an interglacial epoch of this extremely ancient ice age. Glaciated rock pavements somewhat similar to that just discovered, have been recorded from Bacchus Marsh and Derrinal, near Heathcote, in Victoria, Hallett's Cove, and the Inman Valley to the south of Adelaide. In West Australia, although no glaciated pavements have yet been found, there is abundant evidence of the existence there of glacier ice at this Carboniferous period. The evidence of the Irwin coalfield in West Australia is in the form of huge boulders of rock, foreign to the district, up to as much as 60 tons in weight, many of these blocks being scratched and grooved by the old ice-sheets which have used them as "holystones" in the process of grinding down and polishing the rocky floor beneath the ice-sheets over which the thick ice was slowly creeping and exerting enormous vertical and lateral pressure.

Both in West Australia and South Australia there is evidence that the ice-sheets and icebergs ranged northwards to about the parallel of 25° S., that is, within a few degrees of the Tropic of Capricorn. In fact, during this Carboniferous period the whole of Tasmania and the greater part of the southern half of Australia must have been very much in the condition of the South Polar lands to-day. Probably the whole surface of the country within the area specified was covered by glittering sheets of thick ice, with the exception of a few of the higher peaks, such as the great volcanoes of the period, developed on a grand scale in the Lower Hunter region. These erupted glowing masses of lava and grey to green layers of volcanic ash amid the snow and ice of the period, just as Mount Erebus and other active Antarctic volcanoes do to-day. The same exquisite tints of sapphire blue were doubtless to be seen in the crevasses of these very ancient ice-sheets, and the same lovely tints of emerald green around the margin of their floating bergs were doubtless to be observed then as in Polar regions to-day; and in the seasons of summer thaw great rivers sprang into being in a few days and rolled the rock debris of the great volcanoes down into the moraine lakes, and to the margins of the ice-sheets, while the roar of intermittent volcanic eruptions mingled with the thunder of the great avalanches, like those one so often heard and saw rushing down the steep slopes of the Antarctic Andes into Ross Sea.

Previous to this recent discovery near Maitland, the existence of these glaciations before and after the formation of the Greta coal was well known, and an excellent summary of the evidence has been given by Mr. C. A. Sussmilch in a paper published by the Royal Society of New South Wales last year. In the case of evidences of the passage of these ancient ice-sheets over Victoria and South Australia it is possible to determine the direction of movement of the ice by means of the trend of the grooves on the rock floor over which the ice moved, and it may be said that the grooves run generally in a northerly and southerly direction. It remained to decide the "sense" of the movement, that is, whether it had been from south to north or from north to south. In the case of ruts made by wheeled vehicles, one can tell the general direction in which the vehicles have been travelling by the trend of the ruts; but in order to determine the sense in which any particular vehicle has been moving one would have to study the ruts in conjunction with the impression of the horses' hoofs. The latter would at once give the sense of the movement.

In the case of the movement of glacier ice, the place of the hoof-marks, as in the above illustration, is taken by small pieces of rock which have been dragged loose or plucked

by the moving sheet of ice. Thus, small recesses are left where these fragments of rock have been forced off, with little vertical cliffs facing the direction towards which the ice has moved. No such small cliffs with sharp edges could possibly exist if they were opposed to the direction of movement of the glacier ice, as in that case they would rapidly be ground down and obliterated. Another proof as to the direction of movement of ancient ice-sheets is to be found in the character of the large blocks of rock, foreign to a neighbourhood, and known as "erratics". Such blocks have been transported from a distance on top of the ice-sheet or floated by icebergs. It is often possible to discover the exact locality from which such "erratics" have been derived by this method. In the case of the glaciation which followed on after the development of the Greta coal measures, a study of the large erratics found near Branxton shows that they were probably derived from mountains in the neighbourhood of Mount Lambie and the Jenolan Caves.

In regard to the earlier phases of this very ancient Carboniferous glaciation—the phase which preceded the Greta coal measures—the test of the direction of movement of the ice by means of a study of the erratics is inconclusive. The discovery just made by Messrs. Osborne and Browne shows conclusively the exact direction from which the ice came, for not only are there thousands of more or less parallel grooves and scratches on the galciated rock surface at Rockdale, but there are structures, corresponding to hoof-marks, as referred to above, which show the sense in which the ice moved. It came from a little east of south and moved towards a direction north by west.

It would thus appear that the margin of the great continental ice-sheets of Australia in Carboniferous time was situated in New South Wales, near to, or possibly in, what is now the Hunter Valley, extending thence to Currabubula, near Tamworth, and beyond. There is a great development, near the recently discovered glaciated pavement, of the fine-grained flour of rock representing extremely finely pulverized material carried out from under ice-sheets by their sub-glacial streams, and deposited as fine mud in glacial lakes dammed back by mounds of moraine rubbish along the margin of the ice-sheets. These rocks occur usually in delicate paired layers, in some cases as many as from 50 to 100 of these paired layers being counted in a thickness of 1 ft. of rock. The two layers in each pair are of unequal thickness. The thicker layer was deposited by the floods resulting from the summer thaws, and frequently contains small fragments of plant stems and fronds of ferns. The thin member of each set of pairs was deposited during the winter, when the ground was frozen and covered with snow and ice. No remains of plants are found in these thin layers. By counting these paired layers in a given thickness of rock it is possible to tell exactly how many years have been occupied in the deposition of these particular strata. It is estimated that the thickness of about 300 ft. of shales found near West Maitland have taken about 5,000 years to form.

The distribution of the great Carboniferous continental ice-sheets of Australia and Tasmania largely explains why the productive coal measures of the great coal basin of New South Wales appear to be entirely wanting from South Australia, the greater part of Victoria, and Tasmania, as well as from the southern part of West Australia. These southern regions continued to be glaciated long after the edges of the continental ice-sheet had withdrawn from the region of the northern, western, and eastern coalfields of New South Wales, as well as from the region of the Irwin River in West Australia. In areas on the equatorward side of the retreating continental ice-sheet, extensive coalfields of vast value became developed.

PERTH, W.A.

April 24.

Whim Well.—The gold and copper mines of what is generally referred to as the Nor-West were discovered by prospectors returning from the Kimberley rush before the dawn of the eastern goldfields. Metallurgical difficulties in the treatment of the ores, and the scarcity of fuel and timber, have hitherto been against the successful working of the mines on the Pilbara field. However, the rapid decline in the gold-mining areas further south (Murchison and Kalgoorlie) has caused attention to be drawn to the possibilities of the Nor-West. Miners and prospectors are wending their way up, and if the Government will only reduce the heavy taxation and custom dues. many mines will be worked to a profit, The introduction of suction gas plants has made a great difference in the cost of power, especially, as in the case of Whim Well

mine, where fuel has to be imported by boat from a southern port.

On the treatment side two processes have been introduced recently that will help to overcome the difficulties that have militated against the success of this field. The first is the introduction of leaching of the low-grade oxidized ores of copper, while the second, as yet in its trial stages, is the economic extraction of gold in the presence of small quantities of copper, which latter have prevented a good extraction from being obtained by amalgamation and cyanidation. I do not propose to discuss this in the present paper, because sufficient information is not available to the public at present. The question of leaching has been proved to be successful on the Whim Well copper mine, and it opens up big possibilities not only for this mine, but also other similar ore-bodies in the Nor-West.

The Whim Well is the largest copper-ore deposit in the Pilbara field, and a description of it may be of interest. It is situated 56 miles by road to the east of the port of Roebourne, the administrative centre, and 12 miles south from Balla Balla on the coast. There is a tram-line connecting these two points and extending another mile to a safe harbour for lighters. The picked ore and copper are thus railed from the mine, loaded on to the latter, which take them out 7 miles to a well-protected anchorage, there transferred on to boats doing the coastal trading from Fremantle to Singapore. The ore is sent to smelting works in the eastern states or England.

The Whim Well mine was worked intermittently by prospectors for several years, who broke out about 10,000 tons of 15% copper ore, of which they shipped about 4,000 tons averaging 26%. In 1906 the Whim Well Copper Mines, Ltd., took up the property, but had very little capital available. During the following eight years 132,000 tons of 8½% copper ore were broken, of which 57,000 odd tons of 14% average were shipped, while 75,000 tons of rejects of about 4% average were put aside until a suitable treatment became available. During this period a Murex concentration plant was erected for the treating of low-grade oxidized ore. Owing to a number of circumstances it was not an economic success, although an extraction of 80% on 4¾% copper ore was obtained. From 1914 shipping space became very difficult to secure, and not much was done until 1917, when attention was drawn to the successful work being carried out in the leaching of 2½% copper ore at Mount Hope (New South Wales). Experiments were carried out, and in 1920 a start was make to leach a heap of 40,000 to 50,000 tons 4% ore by means of a leaching process known as the Peechy, which will be described later.

The geology has been described in bulletins of the Geological Department, and also in a paper read before the Institution of Mining and Metallurgy on December 21, 1911, by Mr. H. R. Sleeman. I need not describe the geology otherwise than by saying that the ore deposit occurs in grey slaty country which is replaced to the north by schists (altered sediments), which in turn are replaced by earthy travertine limestones, extending to the coast-line. The latter are flanked east and west by extensive granite areas. The ore-body strikes roughly east and west for 3,000 ft. along the crest of a ridge, eventually dipping under the alluvium. The dip is flat (20°) to the north, while there are a number of cleavages running N.W. and S.E. of apparently the same period as the ore-body, as it has not been faulted by them. Along the lines of cleavage, even outside of the main ore-body, copper has been carried in solution and deposited. Typical ironstone gossan overlies the ore deposit, which was no doubt originally pyritic to the surface. The oxidation of the chalcopyrite has left the iron as a capping, while the acid solutions have kaolinized the slate beneath, in which the copper has been deposited as carbonates, oxide, and silicate, with some secondary chalcocite. Owing to the flatness of the ore-body, this action has apparently been local, and there are no lines of ore deposition as shoots. Rich ore has been mined right from the outcrop to the lowest points worked, about 120 ft. below the lowest adit level. At these lowest parts the rich ore is going down as of equal grade as the best parts mined above it.

The development work in the past has been done essentially for the winning of high-grade ore for shipment, and only certain areas have been exploited at all. The result is that it does not lend itself to the estimation or ore reserves in the accepted use of the term.

Mr. H. R. Sleeman has been in charge of the operations for some years, and by his experience of the law of the average value of the faces and level bottoms, together

with the assays from diamond-drill bore holes, he feels justified in estimating the amount of possible ore as a million tons, containing 4% copper. From the outcrop along the line of dip to the vertical depth of 150 ft. below the lowest adit level is 1,000 ft. The main workings extend over a length of at least 600 ft., while the ore-body varies in width from 10 to 50 ft. The total mining to date amounts to 200,000 tons of 8% ore (including pillars left), so that the estimate of the possible amount of pay ore (4%) left in the mine to the bottom level gallons per day of 24 hours, 10,000 gallons were needed for make-up in new parts of the dump at first. The loss was reduced to 4,000 gallons after the circulation was started, and when more complete draining of the dump had been effected. A circulation of twice the above is necessary to make the dump leaching payable. It has been found that 70,000 gallons in circulation will return 10 tons of copper precipitate per month, but with the improvements now effected it is expected that 20 tons per month will be secured by heap leaching, utilizing a

WHIM WELL COPPER MINE.
Vats for experimental work in leaching in the foreground.

is more than twice the amount already taken out.

Hitherto this grade of ore has been unpayable, so that the richer portions have been taken out, while the low-grade ore has been dumped or left in the mine. The experiments carried out for heap leaching were made by Mr. Audley Smith and the mine staff, on the lines of the treatment at Mount Hope, New South Wales. A start was made in 1920 on a 50,000 ton dump of ore, containing 4% copper. A fairly satisfactory result was obtained, but the loss of water was greater than the supply in the mine. It was found that to maintain a circulation of 70,000 circulation of 150,000 gallons of water per day with a loss of 7%. Thus the question of water is a very important one, and an engineer of the Mines Department has recommended that the mine warrants the erection of a five-inch pipe line from Balla Balla to the mine to provide the water necessary for heap leaching, concentration, and leaching of the current ore. The present plant on the mine will be adapted and where necessary expanded to carry out the following treatment scheme, which is based on experiments made.

The ore from the mine is conveyed on a belt to the breaker, from which any high-

grade ore is picked by boys. From there it passes on to rolls crushing to ¼ in. mesh. It is then hydraulically classified, the sands going on to a May jig for concentration, and from thence through an 8 ft. Hardinge pebble-mill, the product going to the agitators with the overflow from the classifier. The fine product is then agitated and leached in Brown agitators with sulphurous acid gas and air from an air-lift, and decanted on the counter-current system used on the gold-fields. As the copper in the solution increases to a suitable percentage, it is sent to the precipitation tanks, which are filled with scrap iron. The excess wash solutions can be used on the heap leaching plant whenever required. The concentrate will be kept up to 20% copper, while the precipitate assays 70% copper, which will be shipped to the most suitable smelters. At the present time the SO_2 is generated from sulphur, but it is intended that before long it will be obtained direct from the pyrites, which has been proved to be of considerable extent below the present workings. The pyrites may also be used on the top of the ore dump, as is done at Bisbee in America, for the rejuvenation of the solutions, thereby increasing their leaching value.

Should this joint scheme of treatment prove up to expectations, it will pave the way for similar work on other copper mines in West Australia, which have hitherto been unable to get a sufficient ratio of shipping ore to that of the low-grade material now shown to be amendable to treatment by leaching.

C. M. Harris.

TORONTO

June 13.

Porcupine.—The gold-mining industry is showing increased activity. The producing mines are increasing their output, much capital is seeking investment, and new properties are being opened up. Attention is being directed to the outlying territory beyond the known gold-producing area, where considerable exploration is being carried on. The Hollinger Consolidated is producing gold at the rate of approximately $200,000 per week, the extraction averaging about $9 per ton. The company has decided to develop its own electric power, and is proceeding with a preliminary survey of the Kettle Falls on the Abitibi River, where it is estimated that 25,000 h.p. may be generated, in addition to 10,000 h.p. reserved by the Ontario Government. The falls lie about 60 miles north of the mine, and the intervening territory presents no serious obstacles to power transmission. The annual report of the Dome Mines for the year ended March 31 shows a considerable reduction in profits due to the unfavourable conditions during the early part of the twelvemonth. Bullion was produced to the value of $1,946,495, the average yield per ton treated being $7·11. The net profits were $302,479, as compared with $951,984 in the preceding year. Operating costs for the first quarter of 1921 went up to $5·05 per ton owing to power shortage, dropping to $3·75 when power again became available in April. General manager Depencier in his report stated that while he regarded it as futile to estimate the value of the ore reserves the developments on the 10th level were considered of extreme importance, as proving the occurrence of highly payable ore at the lowest level opened up. The stamp equipment of the mill, which has not been used for some years, has been put in order for operation, bringing the capacity of the mill up to 1,400 tons daily. The McIntyre has placed an order for an Hardinge ball-mill and other equipment, which will be installed in the fall, bringing the capacity of the mill up from 550 to 900 tons daily. The Hollinger Reserve, lying west of the Hollinger Consolidated, where a high-grade vein system has been opened up at the 300-ft. level, has been purchased by a syndicate headed by E. A. Osler & Co., of Toronto, and development will shortly be commenced. The Goldale Mining Co., which has taken over the Bewick-Moreing holdings, is arranging to carry on an extensive exploration campaign. The North Crown Mine has closed down indefinitely, and it is understood that further financing will be necessary before resuming operations. The Tommy Burns property, about 10 miles south-east from the producing area of the camp, has been taken over by the Triplex Gold Mines. The workings are being unwatered and a new shaft is being put down. Operations have been resumed at the Premier Paymaster, where diamond-drilling has proved the eastward extension of the main vein.

Kirkland Lake.—The Lake Shore during April recovered bullion to the value of $22,213 from the treatment of 1,860 tons of ore, being an average of $11·94 per ton. The mill is kept running on development ore, the policy of the management being to store

up large ore reserves in anticipation of the enlargement of the plant. The Tough-Oakes has resumed underground work with the expectation of commencing milling about August. An important discovery has been made at the 900 ft. level of the Kirkland Lake mine, where horizontal drilling has encountered about 12 ft. of highly mineralized material, 9 ft. of which carries high gold content. A large new ore-body is being opened up at the 700 ft. level. At the Ontario-Kirkland the construction of the mill is making good progress, and it is hoped to have it completed in September. About 3,500 ft. of lateral work has been done on the 300 and 450 ft. levels, indicating a supply of ore sufficient to keep the mill running for three years. The vein at the 100 ft. level of the King Kirkland has been opened up for 172 ft., a considerable proportion of the ore assaying $10 to the ton. Surface exploration is being carried on to determine the most favourable place for sinking a central shaft. The shaft of the Bidgood is being unwatered, and will be put down from its present depth of 300 ft. to deeper levels. A shaft is down 60 ft. on the Lebel Oro on a vein stated to show ore averaging $18 per ton over a width of about 40 inches. A 10 ft. vein carrying good gold content has been found on the Moffatt Hall property, 5 miles from the Tough Oakes. A large syndicate, mainly representing English interests, is bidding for numerous properties lying along the line of the north-easterly strike of the proved gold-bearing zone. Individual claim-holders have been approached with attractive offers for options, and some of the new companies have been offered good prices for their holdings.

COBALT.—Though silver-mining is still depressed by reason of the low price of the metal, conditions are showing some improvement. Towards the close of May the Mining Corporation of Canada resumed operations at full capacity, giving employment to about 250 men. Since closing down the company has increased the capacity of its mill by about 50%, enabling it to treat a higher tonnage and reduce operating costs. The annual report shows profits of $579,569, as compared with $908,748 in 1919. Silver was produced to the amount of 1,664,018 oz., as against 1,230,652, and the ore reserves showed a satisfactory increase, being estimated at 2,181,000 oz., as compared with 1,307,220 in 1919. The amount to the credit of the profit and loss account was $3,268,628. The company covered a wide field in its search for desirable properties, and during the year had about 300 under its consideration. Permanent records embracing 165 of these were prepared, of which 132 were in Canada, 56 of the number being in Ontario, indicating that the Dominion will continue to be the principal scene of its activity. The Peterson Lake, which sustained a considerable loss on last year's operations, and is confronted with heavy obligations, is endeavouring to reconstruct its finances. Its ore reserves are estimated at 126,000 oz. of silver, and the directors believe that if funds for further development can be secured there are good prospects for additional ore discoveries. An important discovery has been made on the Oxford Cobalt, where a number of stringers, one of them carrying 600 oz. of silver per ton, have been encountered 6 ft. below the surface. The O'Brien produced 312,000 oz. of silver during May from the treatment of 6,066 tons of ore, showing an average recovery of over 51 oz. per ton. Lateral work on the Chambers-Ferland property of the Kirkland Lake Proprietary (1919) has encountered an important ore-body averaging 50 oz. of silver to the ton.

VANCOUVER, B.C.

June 9.

GRANBY CONSOLIDATED. — The Granby Consolidated Mining, Smelting, and Power Company has just issued its annual report for 1920. As with the great majority of the other copper companies on the continent, the year has been an unprofitable one, the report showing a deficit of $687,011, which compares with a deficit of $984,409 in 1919. There is this unfavourable difference, however, that in 1919 the company disbursed dividends amounting to $1,312,537, while last year no dividends were declared. The assets of the company were reduced from $25,081,361 to $24,906,360, and the surplus from $1,184,309 to $497,298. The ore-reserve, too, suffered a depletion of 200,000 tons. The last is explained by the fact that in the early part of the year, when the price of copper was good, effort was concentrated on production, at the expense of development. As soon as the 150 ft. level has been enlarged to allow of development to be carried on without hindering production, the boundaries of the ore-body will be extended.

During the year the company produced 25,744,327 lb. of copper, 1,054,206 oz. of silver, and 9,481 oz. of gold. The great

bulk of the silver, probably over 90%, came from ore purchased from the Dolly Varden mine. This ore, which is highly siliceous, acts as a flux for the company's Hidden Creek ores. The average cost of the production of the copper was 15·94 cents per pound, and the average selling price for the 19,464,796 lb. of copper sold was 17·85 cents. Considerable economies were introduced during the latter half of the year, after the change in the management, the cost of production for the first half of the year being 18·38 cents, and for the last half 14·01 cents. Since last fall two cuts have been made in the wage scale, totalling $1·25 per man per shift, and a further reduction in the cost of production has been made this year, the cost for the month of March being 12·44 cents. This reduction is due to increased efficiency on the part of the men, and to improved metallurgical practice, resulting in the use of less coke and flux and in improved extraction,

A. J. Bancroft, professor of geology at McGill University, has taken up his new duties as assistant general manager for the company, and among his first duties will be the extending of the ore-reserve, which now totals 10,986,430 tons of smelting ore. The Governors of McGill University have given Professor Bancroft a year's leave of absence, in which he will decide whether he will take up technical work as a profession or return to pure science at the university.

The company's Cassidy colliery produced 154,000 tons of coal during the year, of which 30% was sold and the remainder converted into coke at the by-product coke-ovens at Anyox, resulting in the production of 75,000 tons of coke. Improvements have been made in the coal-washing plant, and a better grade of coke is being produced.

Standard Mine.—The directors of the Standard Silver-Lead Mining Company have announced that, subject to ratification by the shareholders at a meeting to be held on June 20, they have sold the company's Standard mine for $75,000, of which $25,000 is to be paid in cash and the balance in two equal instalments at one and two years, respectively. A royalty of 20% is to be paid on all ore shipped from the property, such moneys to go towards the purchase of the property. The directors consider that for big-scale operations the mine is worked out, and for the past year it has been in the hands of lessees. The Standard has been an excellent mine, and has payed its shareholders more than $2,700,000 in dividends. The company is in a strong position. If the present sale is consummated it will have a surplus of more than half a million dollars; this is being held for investment in the mining industry in the province, provided a property satisfactory to the directors can be found. It is understood that several properties are under consideration at the present time.

Nickel Plate Mine.—The Hedley Gold Mining Company, owners of the Nickel Plate Mine, at Hedley, has issued its annual report, which shows a deficit of $1,941 on the operations last year. The company realized that the mine was running behind, and, as no satisfactory terms could be made with the employees with regard to a reduction in wages, the mine was closed early last autumn. During the war effort was concentrated on production, and the development, which up to then always had been kept well ahead, was allowed to run behind. Diamond-drilling has indicated that there are extensive ore-bodies awaiting development, and the directors have decided to spend $35,000 in opening up the property for production. The wage scale has been reduced $1·25 per day, so that this work can now be done at a reasonable price.

Premier Mine.—Though the price of labour has been reduced in practically all the mining districts of the Province, the employees at the Premier mine refused to accept a reduction, and on the company attempting to enforce it went on strike. The strike extends to all departments, and includes the work on the concentrator and on the aerial tramway. The company attempted to make a reduction of only 75 cents per day in the wage scale, while $1·25 has been the amount of the reduction in nearly all other parts of the Province. Even if the reduction had gone into force, this would have been the highest priced mining camp in the Province: miners would have received $5·50, shovellers $5·00, and surface labourers $4·75 to $5·00. This is a dollar per shift more than the present rate in the Slocan camp. After being on strike for two weeks the men took a ballot, the result of which was for continuing the strike by a majority of four to one.

Slocan District.—With a view to bringing about renewed activity in the Slocan, the principal silver-lead mining district in the Province, the local branch of the International Mine, Mill, and Smelter Workers met the principal operators and

agreed on a new wage scale, which is a reduction of \$1·25 per day on all classes of labour. Miners and skilled mechanics are now getting \$5·00 per day, mechanics' helpers \$4·50, and labourers and shovellers \$4·00. The result has been that a number of the mines either have restarted operations or are about to restart. The Silversmith Mines, Ltd., owning the principal mine in the district, has made arrangements with the owners of the Ivanhoe mill, by which the Silversmith has acquired the mill, mill-site, and water-rights on the south fork of Carpenter creek. The mill is being overhauled and its capacity brought up to between two and three hundred tons per day, according to the nature of the ore milled. An aerial tramway is to be built to connect the Silversmith with the mill. The mine was closed down on April 1, sufficient ore having been developed to assure a supply for some time. Effort now will be concentrated on the remodelling of the mill and on the building of the tramway, and when this has been completed it is probable that the mine will be reopened.

The Yukon.—Several hundreds of tons of supplies, mining machinery, and building material are accumulating at Whitehorse for shipment to the new silver-lead camp at Mayo. It is expected that the river will be in condition for moving this towards Mayo Landing by the end of the second week in June. The Yukon Gold Mining Co. and the White Pass Railway Co. are building wharves at Mayo Landing.

Alberta.—A bill has passed the Dominion House providing for the incorporation of the Mackenzie River Railway Company, Ltd., with a capital of \$10,000,000. It is understood that the Imperial Oil Company is substantially behind the project. The railway will extend the Alberta and Great Waterways system from Fort McMurray, where the rails now end, to Great Slave Lake.

Considerable excitement has been caused by the discovery of alluvial gold in the banks of the creek running into the Cadotte river, which flows into the Peace river about 40 miles below Peace River town. The new discovery is 75 miles from Peace River town. The original discovery was made by an Indian trapper, who brought nuggets into the town. Dr. Gauthier and a party set out for the location, and after doing a little excavating and panning were convinced with the value of the discovery, staked claims, and filed them in the land office at Peace River.

LETTERS TO THE EDITOR

Wave-transmission Rock-drills

The Editor:

Sir—I note that Mr. Chas. R. Love objects to the loss in the transmission cables which I had assumed in my comparison between the boring capacities of the wave-motion rock-drill and the pneumatically operated tool per i.h.p. installed at the surface.

This matter has very little bearing on the point at issue, and the loss in transmission can be reduced to any reasonable extent by increasing the sectional area of the conductor employed, the cost of the cable being the only factor of commercial interest.

Similarly, Mr. Love may certainly generate the current at the voltage he prefers, and thus do away with the necessity for the use of underground transformers, but I hold that it is not good commercial practice to use low voltages in transmission lines, owing to the great cost of the extra copper required in the conductors. The voltage might easily be reduced to one-half, one-quarter, or one-tenth of that which I should propose to use (3,000 volts), but in that case the cost of the cables will have to be multiplied by two, by four, or by ten, as the case may be, and even in the very limited area of a mining concession, the extra expense will be a formidable item.

With regard to Mr. Love's statement that I have been comparing a wave-power plant of 12 h.p. with a compressed-air plant of 1,000 h.p., I must protest altogether, and I think that Mr. Love has overlooked a certain very important difference between the two systems.

If the pneumatic system is to be installed on a mine, the whole compressing plant may be set up at any convenient place and the compressed air led to any workings within the limits of the property without regard being paid to the lateral extent of the workings or to the differences in altitude between the compressor and the rock-drills which have to be operated by it.

It is quite otherwise with the wave-power plant, as the generators and the drills which they are to operate must be installed within reasonable lateral distance of each other, and it is essential that the difference in vertical height between the wave-motion generators and the rock-drills must be strictly *limited.*

This means that any ordinary mine would require many separate installations at various depths in each shaft in which the drills are required. The wave-motion generators must therefore be constantly moved from place to place and this calls for small units which must be easily transportable.

Certainly bigger units than 12 h.p. each might be used if they can be built sufficiently compact, and not too heavy for easy transportation *in the shafts*, but I am not aware that anything larger than the 12 h.p. unit has, so far, been built, nor do I see outside the somewhat better efficiency of the larger electric motor which would be required, any real advantage to be gained, as there is no reason to expect the efficiency of the wave generator to be increased to any serious extent by doubling or trebling its capacity.

Since the compressed-air installation does not call for subdivision into small units, the case of the 12 h.p. air-compressor does not arise, and I can only repeat that, in my opinion, the wave-power rock-drill is not a serious competitor to the compressed-air drill for mining purposes from any point of view.

In conclusion I must deny that I have treated the wave-motion system at all unfairly in my previous letter; in fact, I consider that I have been more than generous to it by crediting it with a boring speed very much in excess of that which I believe it to be capable of, nor have I touched upon certain other disadvantages which I believe to be inherent to the system, and which would surely cause trouble and inconvenience in ordinary mining use.

R. DE H. ST. STEPHENS.

Camborne, *June* 25.

PERSONAL

REGINALD F. ALLEN is now engaged at the Kingsdown (Hewas Water) tin mine, St. Austell.

E. C. ANDREWS, Government Geologist for New South Wales, has been elected president of the Royal Society of New South Wales.

ERNEST BOTTOMS is home from Nigeria.

SIR JOHN CADMAN has been elected president of the Institution of Mining Engineers.

J. MORGAN CLEMENTS has returned to New York from China.

F. G. COTTRELL is in Europe investigating helium and oxygen production on behalf of the United States Bureau of Mines.

N. F. DARE has been appointed manager for the Chenderiang Tin Dredging Co., Ltd., in Perak, Federated Malay States.

ALLAN DAVIDSON has returned from Nigeria.

ARTHUR DICKINSON is back from Brazil.

R. W. FFENNELL has returned to South Africa.

T. R. HAMBLER is home from Nigeria.

R. W. HANNAM is home again from Nigeria.

Dr. J. A. L. HENDERSON has moved his office to College Hill Chambers, College Hill, Cannon Street, London, E.C. 2.

JAMES HOCKING has returned from Spain.

ARTHUR W. HOOKE has gone to the United States on a short visit. As representative of Inder, Henderson, & Dixon, he will inspect some alluvial gold deposits in the Seward Peninsula, Alaska.

ALFRED JAMES has resigned from the Council of the Institution of Mining and Metallurgy.

FRED JOHNSON has been elected president of the Birmingham Metallurgical Society.

RICHARD L. LLOYD, of the Dwight & Lloyd Metallurgical Company, has been awarded the degree of Master of Science by the Washington University, St. Louis, U.S.A.

ROSS MACARTNEY is expected from Rhodesia.

S. M. MARSHALL has returned to New York from India.

JOHN MATHIESON and the other members of the Scottish Spitsbergen Syndicate's expedition arrived at Spitsbergen on June 16.

WALTER G. PERKINS has returned to his old address at 62, London Wall, London, E.C. 2.

ALEXANDER RICHARDSON is leaving for Canada and the United States, where he will visit mines and mining schools.

SIR MARCUS SAMUEL, head of the Shell Group, has been made a peer, and is now known as Lord Bearsted.

EUGENE SCHNEIDER, the iron-master of Creusot, France, is to be the John Fritz medallist for 1922.

W. E. THORNE has left for Nigeria.

W. D. THORNTON has moved his office to the new Cunard Building, 25, Broadway, New York.

J. R. THURLOW is here from the Rand.

R. P. TOD, who has been for many years in charge of the British Aluminium Co.'s works at Kinlochleven, has joined the staff of Sir W. G. Armstrong, Whitworth & Co., Ltd., where he will be occupied with the firm's hydro-electric work.

LOUIS A. WRIGHT is on a short visit to Spain.

The summer meeting of the Mining and Metallurgical Golfing Society was held at the links of the Highgate Golf Club on June 28. The first prize was won by EDWARD HOOPER (90 − 11 = 79 net) and the second by W. H. STENTIFORD (100 − 16 = 84 net).

ARTHUR L. PEARSE died at New York on May 14.

SIR BERNARD OPPENHEIMER died on June 12, after having been in indifferent health for over a year. He was head of the South African Diamond Corporation. It will be remembered that he established several diamond cutting works in this country, where he employed disabled soldiers.

SIR THOMAS WRIGHTSON, BART., chairman of Head, Wrightson & Co., Ltd., Stockton-on-Tees, died on June 18, aged 82. He was born in 1839 near Darlington, and received his education at King's College, London. He served an apprenticeship at the Elswick Works, Tyneside, of which his cousin, Sir William G. Armstrong was then the head. He also spent some time in civil engineering at Westminster with Sir John Fowler and Sir Benjamin Baker. In 1864, he went to the ironworks of Head, Ashby & Co., Stockton, which shortly after became known as Head, Wrightson & Co., Limited. He contributed many papers to the proceedings of the

Iron and Steel Institute. He was interested in many other departments of science than engineering and steel manufacture. His work in connexion with the physiological theory of hearing and the structure of the ear was of high order and was well received among physicists and in medical circles.

TRADE PARAGRAPHS

SALTERNS, LTD., of Parkstone, Dorset, send us a pamphlet on the development of water power, describing their water turbines and accessories.

The GENERAL ELECTRIC Co., LTD., of Magnet House, Kingsway, London, W.C. 2, send us a pamphlet describing the "Kingsway 11" miners' electric hand-lamp

The CRESSALL MANUFACTURING Co., of 40 and 41, Staniforth Street, Birmingham, have issued a leaflet describing their controller resistances for cranes, lifts, hoists, etc.

THE CONSOLIDATED PNEUMATIC TOOL, Co., LTD., of 170, Piccadilly, London, W. 1, send us leaflets describing electric grinders, air and electrically operated coal drills, and the Boyer hammer-pick.

JOHN MILLS & Co., of the Railway Foundry, Llanidloes, Montgomery, send us a catalogue relating to their steam-driven self-contained hauling engines. The catalogue contains full illustrations and descriptions of the standardized spare parts.

BRUCE PEEBLES & Co., LTD., manufacturers of electrical machinery, Edinburgh, announce the appointment of Arthur T. Smith as their representative in the Midland Counties of England, and of Harold E. Webb as their London office manager.

THE MITCHELL VIBRATING SCREEN, invented by B. A. Mitchell, chief engineer to the Utah Copper Company, is being placed on the market by the Stimpson Equipment Company, of Salt Lake City, which is represented in the country by Stephen M. Holden, 42, Bannerdale Road, Abbeydale, Sheffield.

THE WESTINGHOUSE ELECTRIC INTERNATIONAL Co., of 165, Broadway, New York, and 2, Norfolk Street, Strand, London, W.C., send us their monthly house organ for June and July, and also pamphlets relating to the electrification of excavating shovels, electric arc welding, electrical apparatus for the metallurgical and chemical industries, the electrical precipitation and recovery of dust, smoke, and fume from gases, automatic railway substations, and the electrification of steam railways.

SIR W. G. ARMSTRONG, WHITWORTH & Co., LTD., announce that they have secured the services of R. P. Tod, M.I.Mech.E., M.I.Met., in connexion with their hydro-electric work. Many of our readers will have met Mr. Tod on visits which they have paid to the British Aluminium Co.'s works at Kinlochleven, where he has been since 1907, and where originally he was in charge of the erection of the pipe-lines and turbines of 30,000 h.p. Mr. Tod has, until recently, been manager-in-chief over the whole of the British Aluminium Co.'s undertaking at Kinlochleven.

SOZOL, LIMITED, of 20, Copthall Avenue, London, E.C. 2, send us samples of their anti-rust and anti-corrosion preparations. These liquids form a film on the metal surface in the nature of an adsorption or molecular effect, and the film is not easily removed mechanically, though it is amenable to soap and boiling water. Sozol ought to be of great value to the engineer in charge of mine plants and stores. Elsewhere in this issue we quote the covering patent, granted to Professor Edwin Edser and Otto Reynard. The proprietary company is controlled by Minerals Separation, Ltd., and the sale agents for the United Kingdom are F. Simmonds & Co., 1 to 3, Regent Street, London, S.W. 1.

HILL & Co., ENGINEERS, LTD., of 7, Hobart Place, London, S.W. 1, showed the Sauerman cableway excavator at the recent Building Trades Exhibition at Olympia. This excavator consists primarily of a scraper bucket attached by flexible chain connexions to a patented type of carrier running on an inclined track cable, this cable being supported at the upper end by tension blocks to a well-guyed mast and anchored at the lower end to a movable A-frame or bridle anchorage. A load cable is attached to the front of the bucket and carrier. This cable performs the operation of loading the bucket and conveying it along the track cable to the dumping point. A tension cable is provided for operating the tension or fall blocks at the top of the mast or tower. This cable and the blocks tighten and slacken the track cable. Both the load and tension cables lead from guide blocks at the top of a mast or tower down to a double drum friction hoist, usually located at ground level. The machine is designed for excavating and conveying sand, iron ore, or gravel, and will dig, elevate, convey, and dump the material in a continuous operation under the control of one man

METAL MARKETS

COPPER.—The standard copper market in London exhibited a fairly steady tendency during the first half of last month, but during the latter half weakness set in and values receded. The settlement of the coal dispute, however, caused a better feeling at the end of the month. The easier tone was in sympathy with weaker American advices, holders in the United States showing greater willingness to cut prices than had been the case for some time. A simultaneous fall in the value of the pound sterling in New York failed to give London quotations any support. Sentiment during the month was inclined to be somewhat variable, according to whether the coal news was favourable or unfavourable in regard to a speedy termination of the stoppage. The demand from British consumers has been poor, and is certainly unlikely to revive until coal supplies are again plentiful. Inquiry from the Continent at the beginning of the month was moderate, but had a slackening tendency later, although Germany continued to feature as a buyer on a fair scale. It is interesting to note that Germany was the largest single importer of copper from America during April, taking 7,000 tons, while France took 4,500 tons and the United Kingdom 3,600 tons. Italy appears to have purchased more rough copper for sulphate-making than she actually needed, and it is quite possible that she may find herself compelled to make resales. Advices from the United States indicate that production there was only 46,000,000 lb. in May against 90,000,000 lb. in April, and it is estimated that by July the figure should not be more than 35,000,000 lb. On this basis it is expected that the second half of the current year should witness a considerable reduction in the existing large stocks of electrolytic copper in the United States, as consumption should then far exceed the restricted production.

Average price of cash standard copper: June, 1921, £71 18s. 2d.; May, 1921, £73 5s. 10d.; June, 1920, £88; May, 1920, £96 18s. 1d.

TIN.—Despite temporary rallies, the standard tin market during June was characterized by a weak tendency, and values closed the month considerably below the opening quotations. The prolongation of the coal stoppage, combined with general industrial depression and unfavourable reports from the American market, made this downward movement almost inevitable. Professional dealings on 'Change constituted the bulk of the business transacted, in the absence of any appreciable consuming demand. The tinplate works have been taking practically nothing, but it is believed that their stocks are low, and that they will find it necessary to make fair purchases when operations are resumed on a larger scale. In the meantime, the outlook is obscure and it is difficult to take a really favourable view of the market. In America business is dull, and although dealers there have been making purchases both in the Straits and China, the motive appears to have been the acquisition of stocks rather than the satisfaction of demand. The rise in the dollar might have been expected to bring in some American buying on the London market, but this did not materialize. In the East holders have been more willing to sell, and there is a suspicion that producers are finding it difficult to dispose of their current production, with the result that the large stocks held there by the various interests are still being added to. While the tin market is a notoriously erratic one, it seems rather unlikely that it will assume a very firm appearance while general conditions are so unfavourable, although, of course, the cessation of the coal stoppage may cause fresh optimism in the near future.

Average price of cash standard tin: June, 1921, £167 12s. 10d.; May, 1921, £177 10s. 8d.; June, 1920, £250 18s. 6d.; May, 1920, £295 3s. 7d.

LEAD.—The London lead market kept very steady during June, although business at times was quiet. Spain continued to be practically the only source of supplies for the London market, and in this connexion it is interesting to note that some Spanish mines at least are able to sell at a profit at current prices. The other producing countries, however, have been sending very little. Nothing can be expected from Australia at the present time, and there is little chance that Burma will have any metal to spare. Germany may, of course, find it possible to ship some metal in the near future, but at the present time—whatever the reason—is adopting a waiting policy. In Mexico the Government seems to anticipate a revival of activity as soon as conditions are more favourable, and large quantities of ore are being dispatched to the smelter of the American Smelting and Refining Co. at Chihuahua in readiness for the resumption of operations, whenever that may be. The price in the United States has been easy of late, having fallen from 5 cents to 4·50 cents per lb., which increases the possibility of offerings in London from that quarter, although the recent rise in the dollar militates against such sales. In the meantime, arrivals from the chief exporting country, Spain, continue somewhat irregular owing to bunkering difficulties. Consumers here have generally bought for prompt delivery in furtherance of their policy of only taking metal for their immediate requirements, and their doing so has probably helped to keep the market firm by creating a premium for prompt metal. In the United States there appears to be some reluctance on the part of producers to curtail mining operations because of the good price obtainable for the silver recovered.

Average price of soft pig lead: June, 1921, £22 9s. 1d.; May, 1921, £23 7s. 3d.; June, 1920, £35 1s. 4d.; May, 1920, £39 3s. 2d.

SPELTER.—The London spelter market fluctuated during the past month, but values on the whole were fairly steady. Despite the poor industrial outlook, there was an absence of selling pressure. Consuming demand, of course, was restricted, owing to the poor state of the galvanizing trade and the coal stoppage, but, nevertheless, there was a steady though small inquiry. The attitude of the Continental producers appeared to be quite firm. Germany offered very little, being hampered by the reparations legislation and by the troubles in the zinc-producing province of Silesia, while Belgium and Norway were not disposed to make sales

at the expense of prices. Production in Belgium during May was 4,360 tons, or 40 tons more than in April. In America the market has been quiet and easy, with consuming demand poor, although both India and Japan have made purchases there. The United States output in May has been estimated at 18,000 tons, or about 1,500 tons more than in April, and 2,300 more than in March. Deliveries during May amounted to 14,000 tons, so stocks were increased during the month by some 4,000 tons. It would appear that the current yearly production of America is the lowest since 1904.

Average price of spelter: June, 1921, £27 2s. 2d. May, 1921, £27 6s. 7d.; June, 1920, £40 2s. 11d.; May, 1920, £46 0s. 9d.

ZINC DUST.—The market is quiet and moderately steady. Australian high-grade zinc dust is quoted at about £55, and English 92 to 94% is priced at £53, but other makes are obtainable around £52.

ANTIMONY.—Ordinary brands of English regulus are still quoted at £37 to £40, special brands at £38 5s. to £42, and 98 to 99% at £29 to £32. Foreign is quoted at about £24.

ARSENIC.—Business is dull, and the quotation nominal at £46 to £48 per ton, delivered London or Liverpool.

BISMUTH.—The price has kept very steady at 7s. 6d. per lb.

CADMIUM.—Sellers have made no alteration in the quotation, which continues at 6s. to 6s. 3d. per lb.

ALUMINIUM.—British producers continue to quote £150 per ton for both home and export business, but foreign metal is obtainable at considerably below this figure.

NICKEL.—The price was advanced £5 during the month to £190 for both home and export.

COBALT METAL.—The quotation remains at 15s. to 16s. per lb.

COBALT OXIDE.—There has been no recent change in prices, black oxide being quoted at 12s. and grey at 13s. 6d. per lb.

PLATINUM AND PALLADIUM.—Prices have kept steady, raw platinum being obtainable at about £17 and raw palladium at £15, while manufactured metal is quoted at £20 per oz in both cases.

QUICKSILVER.—Values have had an easier tendency, and the present quotation is about £11 per bottle.

SELENIUM.—The quotation is unchanged at 10s. 6d. to 13s. per lb.

TELLURIUM.—The price continues at 90s. to 95s. per lb.

SULPHATE OF COPPER.—£30 per ton is quoted for both home and export business.

MANGANESE ORE.—The market has had a slightly easier tone, and Indian grades are quoted at 1s. 2½d. per unit c.i.f. U.K

TUNGSTEN ORE.—This market has continued dull and variable. We call the price of 65% WO_3 about 10s. 6d. to 12s. per unit c.i.f.

MOLYBDENITE.—The price is somewhat easier at 42s. 6d. to 50s. per unit c.i.f. nominal.

CHROME ORES.—Values have tended to weaken, and Indian and African grades are now quoted at £4 10s. to £5 per ton c.i.f.

SILVER.—The tendency was upwards during the month. Spot bars opened at 33½d. on the 1st, rose to 35⅝d. on the 11th, weakened to 34⅝d. on the 16th, recovered to 35⅝d. on the 20th, and closed on the 30th at 35⅜d.

GRAPHITE.—Sellers continue to quote Madagascar 80% to 90% at £20 to £25 per ton c.i.f.

IRON AND STEEL.—The prolongation of the coal strike continued adversely to affect the iron and steel trades. Stocks of pig iron have diminished, and premiums have been asked for July delivery where obtainable. With the strike over, pig iron producers will only restart their furnaces again if the settlement includes terms which will allow of cheaper fuel. In the meantime, Continental material has been coming over at cheap prices, Belgian foundry iron being offered at £5 c.i.f. U.K., against the official minimum home trade price for No. 3 Cleveland of £6. The depression in the finished iron and steel trades has continued, and though makers will now be able to resume operations provided fuel and raw material are cheaper, few have sufficient orders for one week's rolling. In the meantime, orders have been lost to Germany, Belgium, and the United States.

THE MINING DIGEST

A RECORD OF PROGRESS IN MINING, METALLURGY, AND GEOLOGY

In this section we give abstracts of important articles and papers appearing in technical journals and proceedings of societies, together with brief records of other articles and papers; also notices of new books and pamphlets, lists of patents on mining and metallurgical subjects, and abstracts of the yearly reports of mining companies.

RECOVERY OF ZINC FROM LEAD SLAGS

The *Proceedings* of the Australasian Institute of Mining and Metallurgy, No. 38, 1920, contains a paper by Guy Courtney on the recovery of zinc from lead blast-furnace slags, giving a description of some of the work carried out by the Sulphide Corporation at Cockle Creek. Early in the life of the works it was realized by the metallurgical staff that a very wide field for investigation lay before them. At the head of these was the late F. H Evans, and it was due to his work and suggestions that the question has grown from a mere hypothesis to a commercial undertaking, in so far as these works are concerned. In 1908 a patent was filed by Mr. Evans in conjunction with P. A. M'Kay, which had for its object the expulsion of zinc from lead blast-furnace slags, the operation being carried out either in a blast-furnace or reverberatory furnace supplied with tuyeres. A converter was also proposed, the reduction of the zinc being accomplished by blowing in carbonaceous material in a finely divided condition, or carburetted gas through the molten slag. One of the earliest attempts made at Cockle Creek to drive the zinc from the slag was some fourteen years ago. Compressed air was blown in under the surface of some molten slag. The resultant ebullition drove off large volumes of fume, but, owing to the chilling effect of the cold air, the test could only be maintained for a few minutes. A little later this method was again tried, with certain modifications. An iron pipe was lined with firebrick, leaving an opening 15 in. in diameter and 4 ft. deep. Four inches from the bottom three tuyeres were fitted, equally spaced round the circumference. Attached to the tuyeres were three reservoirs for powdered coal. In starting, the air and coal dust were turned on and hot slag poured in to a depth of about 12 in. above the tuyeres. The agitation, brought about through the blast of air and the combustion of the coal, drove off dense volumes of fume. This continued without abatement for about 45 minutes, which was as long as the supply of fuel lasted. Without proper means of handling the powdered coal, it became a difficult matter to ensure a constant stream being blown in with the air, as at this period little was known of the methods and appliances now in use for the handling of powdered fuel. The zinc driven off was only about 1%, but a marked increase in the temperature of the slag was observed. This would no doubt have reached 1,600° C., which was afterwards found to be so important a figure in all the tests. When this experiment was repeated the same results were observed. These tests anticipated the patent subsequently taken out, and in a great measure the new methods now being employed in one or two American and Japanese works, whereby powdered fuel is fed to the copper blast-furnaces through the tuyeres.

At a later period information was obtained from Europe, which led to the belief that the problem had been successfully solved there. Two processes were in operation: one using briquettes in a blast-furnace, the other utilizing the hot slag as it was tapped from a lead blast-furnace into a reverberatory furnace. In the latter operations two reverberatory furnaces were used, one of 20 tons and the other of 5 tons capacity. Into the former the slag was tapped from the blast-furnace and given a good strong firing. At intervals of 2½ hours the tap-hole was opened and enough slag allowed to run to fill the smaller or 5 ton reverberatory. At this stage a certain amount of limestone and coke was added, and the charge strongly fired for another 2½ hours. At the end of this period the zinc should have been expelled from the slag.

An experiment at Cockle Creek on the reverberatory method differed from the European tests in that only one furnace was used and the slag was introduced cold instead of hot. Charges of 10 tons were treated in this way, and a fair quantity of fume was expelled. One of the conditions necessary for the success of the operation was that the temperature should be not less than 1,600° C. A fair amount of fume came away while the slag was melting. A period of quiescence then intervened, when the fume came off again in large volumes, on the temperature rising to 1,600° C. Agitation of the charge helped considerably, but this agitation had to be continuous to be effectual. From assays taken it was found that from 35% to 40% of the zinc was expelled. The cost of working this method was, however, found prohibitive. A large amount of labour was necessary, and the quantity of fuel consumed in maintaining so high a temperature placed it beyond the possiblity of being a commercial success. Attention was next turned to the advantages offered by the electric furnace. A 350 k.w. motor-generator set, capable of giving 7,000 amperes at 50 volts, had been installed for treating zinc ores electrothermically. A small furnace was built of circular section, lined with 9 in. of English firebrick and holding about 500 lb. of slag. The top was left open so that the progress of fusion could be followed from beginning to end. Early during the test it was noticed that the action of the slag on the lining was very drastic, and at the end of six hours nothing remained of the furnace but the outer iron shell. As this was more of a preliminary experiment than an actual test, no figures were taken of power consumption or zinc extraction, though it was observed that dense volumes of fume were evolved. Numerous other linings were tried, including chrome and magnesite, but the experience gained was identical in each case; no refractory material could stand the intense heat and the action of the slag. Finally recourse was had to a water-jacketed furnace. A tank was therefore constructed, of trough form, 14 ft. long and 2 ft. wide, having a two-course brick lining, the idea being to have a furnace in which the molten slag would be kept in a state of flow, thereby endeavouring to establish a continuous operation. Four electrodes were introduced at equal intervals through the roof, the carbon tamping in the hearth making the

negative side. Cold slag was fed at one end, and, on fusing, travelled to the other end of the trough, having to pass three intensely hot zones on its way to the tap-hole. Continuous charging and tapping were maintained with excellent results, a large tonnage being treated with an extraction of 60% of the zinc in the slag. When the furnace was dismantled it was found that in the space formed, due to expansion, between the inner and outer lining of bricks, about half-a-pound of metallic zinc had condensed. This led to the conclusion that, under suitable conditions, it should be possible to condense the fume by the same operation, and thus save the additional cost of retorting. In order to collect the fume a new furnace was built, consisting of two concentric rings of boiler plate having a 3 in. water space between. A set of flues, connecting to a fan and bag-house, was erected and 10 tons of oxide collected. In appearance the oxide was somewhat grey, though occasionally there would be periods when the product from the bags would be nearly white. The carbon content explains the difference in the colour, but no reason can be assigned as to why it should be more prevalent at some periods than at others. The oxide produced by this method, it was observed, was of greater density than that recovered by the blast-furnace process of extraction mentioned later; it would be reasonable, however, to expect a good deal more occluded air in blast-furnace oxide than in that produced electrothermically. The following is a percentage analysis of the electric-furnace oxide: $PbSO_4$, 15·12; $PbCO_3$, 5·00; ZnO, 62·8; Fe_2O_3, 0·7; Al_2O_3, 2·21; SiO_2, 4·07; C, 0·93; CaO, trace; As, trace. In all cases a resistance type of furnace was used, this giving the highest efficiency. Besides using cold dump slag several tests were made on hot slag direct from the blast-furnace, as it was considered that by utilizing the heat already in the slag a great saving in power could be effected. The contrary was, however, found to be the case, as shorter time is required to remove the zinc from cold slag than when using it hot. Reducing agents and fluxes were discarded, as no advantage could be found to result from their use. There is no doubt that, given cheap power and a moderate price for graphite electrodes, the extraction of zinc from lead blast-furnace slags of low zinc contents could be looked upon as a commercial possibility, those usually run and experimented upon at the works containing about 9% Zn.

After a lapse of three years the question was again brought to the fore, and after careful consideration a small blast-furnace was constructed. Two rows of tuyeres were allowed for, 15 in. apart, with the bottom row 9 in. above the bottom of the furnace, the area at this point being 4 ft. 6 in. by 2 ft. 3 in. The depth of shaft from tap-hole to feed floor was 9 ft. 3 in., while above the feed floor a large chamber was built for the cooling of the gases before passing to the flues leading to the bag-house. The original tuyeres, 3 in. diameter, were found to be too large, therefore cast-iron thimbles were used to reduce the size to 1½ in. diameter. Soon after starting it was found that the two rows of tuyeres were rather a disadvantage, a careful balance in the blast pressure having to be maintained, otherwise a back draught was produced in the top row, which quickly destroyed the sleeves on the bustle pipe. At the same time an element of risk was run by the men attending the furnace when they opened the tuyeres, and as a consequence the top row was discarded. A 5 ft. charge column was found to give the best results when working with a blast of 8 to 10 oz. By these means it was possible to run the furnace with a hot top, while at the same time a minimum amount of dust was blown into the flues. From the cooling chamber the fume was carried along 30 ft. of brick flue and 180 ft. of 40 in. diameter iron pipe to a Fichter fume-collecting plant, and from thence to the bag-house. The Fichter plant, owing to the poor condition of some of the elements, on account of their having been idle for some years, did not collect much fume, but it answered the purpose of a cooler, the gases being so hot that the original arrangement, whereby the fume went straight to the bag-house, did not allow sufficient length of pipe and in consequence many of the bags were destroyed. The bag-house consisted of five rows of 12 bags, each 18 in. diameter and 17 ft. long. Two qualities were used, unbleached calico and grey flannel, the latter having the longer life. A by-pass was introduced between the furnace and the bag-house, by which means it was possible to divert the fume to the smelter stack, in the event of the bags requiring repairs or renewals. At the same time, as the capacity of the fan in use was not large enough to take all the fume, it was possible to run the furnace at full capacity, likewise preventing any fume from blowing through the charging doors, and interfering with the feeding.

In order to thoroughly test the method three distinct charges were used: slag briquettes, slag nodules, and ordinary dump slag. The first to be used were the briquettes having the following composition: Crushed slag, 100 parts; limestone, 15 parts; coke, 15 parts; cement, 1·5 parts. From the outset a great deal of trouble was experienced, through the friable nature of the briquettes, which broke up in the furnace and filled the crucible and tuyeres with fines. It was also found necessary to add an additional 26% of coke, part of which went to make up for the amount of fine coke blown out of the furnace. Quite apart from these mechanical troubles, however, the cost of making briquettes was found to be too high to ensure a profitable undertaking. In dealing with the slag nodules, all the above-mentioned objections also applied, but in spite of the many difficulties encountered, some valuable data were collected. The assay of the charge gave: lead, 3·6%; zinc, 7·8%. The zinc is on the low side, which is, of course, due to the dilution of the slag by the fluxes. The slag tapped ran on an average 0·5% lead and 3·2% zinc, the recovery calculated on these figures being 70% lead and 60% zinc. The high lead content of the slag is accounted for by the fact that it was taken from an old section of the dump. During all the operations a great deal of trouble was experienced through the formation of sows, but by building the crucible with a slope in the direction of the tap-hole, this trouble was overcome. The treatment of the nodules was a replica of the briquette campaign, only of shorter duration, giving practically the same results. Following the briquettes and nodules, a trial was carried out with slag direct from the dump. A certain proportion of limestone was added in order to run a slag going about 25% CaO. The following is the composition of the average charge: Slag, 100 parts; limestone, 17 parts; coke, 34 parts; with 2·3% Pb

and 9·8% Zn. The tapped slag went 1% Pb and 5·4% Zn. The recovery on these figures gives 60% Pb and 41% Zn. These results are low, but from data obtained while using a small quantity of slag rich in zinc, it was found possible to maintain a recovery of about 75%, and it was also found to be a comparatively simple matter to reduce the zinc to about 5%, regardless as to whether the original contents were 9% or 15%, so that, in running on a slag going 15% or 20% Zn, a fair margin of profit would be shown. About 40 tons of oxide of a blue-grey colour were collected which, on ignition, appeared creamy-white and gave the following percentage analysis: PbO, 25·42; ZnO, 63; CaO, trace; Insoluble, 0·70; SO_3, 8; Sb_2O_3, 0·13; As_2O_3, 0·85; Fe_2O_3, 0·28; CuO, trace; and Cl, 0·014.

From this series of tests certain definite data were established, showing that, in order to successfully recover zinc from lead blast-furnace slags, the zinc in the original slag should not be much below 15%. In addition it was found that a large proportion of the zinc is evolved during the process of melting; hence cold slag is preferable to slag in the molten state to commence with. The slag having reached the molten stage no more fume comes off until the temperature attains the region of 1,600° C or over. A lower temperature can be used, say 1,200° C, provided the bath is kept in a state of constant agitation during the whole period of treatment. These points concerning critical temperature were established through the medium of the electric furnace, which proved particularly suitable for this class of work, where a condition was required at all times that would permit of a close and constant watch being kept on the operations as a whole, but more particularly on the bath of slag itself. In order to carry the experiments through to a finality a small electrolytic zinc plant was erected for the treatment of the oxide. The plant was capable of producing about one ton of zinc per day and the whole of the oxide was converted to metal, which presented no difficulties in operating beyond those usually encountered in converting oxide to metal electrolytically, a high-grade zinc being produced.

MINING IN CENTRAL AUSTRALIA

In the *Chemical Engineering and Mining Review* (Melbourne) for March and April, E. Copley Playford, Chief Warden at Darwin, Northern Territory, gives an account of his journey from Adelaide to Darwin across the continent of Australia.

With the exception of a small and unprospected belt 80 miles south of Alice Springs, no metalliferous rocks are met with between Oodnadatta and the Macdonnell Ranges. Near Charlotte Waters, close to the Territory boundary, there exist deposits of kaolin, one apparently of great length and width, and of a very pure nature, from which aborigines obtain material to make smoking pipes and carved ornaments for the purpose of barter. An analysis of samples of clay taken by the writer from this deposit show the quality to be good and its behaviour, when burnt, fits it for use in high-grade ceramic ware. Arrangements have now been made to have a bulk parcel sent to the school of mines, Ballarat, where the Institute of Science and Industry is assisting in carrying out research work on clays of various types.

The Macdonnell Ranges consist of a series of jagged, precipitous, and, comparatively speaking, parallel lines of peaks, low jumbly hills and ridges rising from a plateau ranging from 2,000 to 2,500 ft. above sea-level, the mountainous and hilly country partly enclosing some extensive cotton and saltbush and grassy plains. These ranges trend in an easterly and westerly direction for about 250 miles with an average width of 45 miles, the overland telegraph line crossing them at their central and narrowest part. Apart from such crossing, the only sections passed over by the author were from Alice Springs via Undoolya station to the Arltunga goldfields, and from the latter locality via Winnecke goldfield, back to Alice Springs. The rocks, metamorphic and igneous, along the whole of the latter route, are favourable for the occurrence of gold, but except the auriferous areas mentioned and the Hart's Range mica field, very little prospecting work has been carried out throughout the Macdonnell Ranges.

The White Range, Arltunga goldfield, lies in the Macdonnell Ranges, about 60 miles E.N.E. from Alice Springs telegraph station, and 280 miles north from Oodnadatta railway station. The properties that have been worked comprise 16 gold-mining leaseholds with an aggregate area of 640 acres. With the exception of some of no great extent or depth on a claim known as the Joker, all mining operations that have been carried out on the White Range are within the boundaries of the leaseholds taken up by White, and nearly all are on its eastern slope, the majority being within an area of 80 acres. The principal ones, ranging from north to south, are locally known as the Great Western, Associated, White's East, and Lucy, with its continuation westerly known as the Pipeclay, White Range Consolidated, Excelsior, and Extended Nos. 1 and 2. There are also other mine workings on the higher slopes of the range and some near Corby's Bluff. Of these the most extensively worked are the Excelsior and Lucy, but in these two, as well as all the others, the ore has been simply rooted out at depths up to 70 ft. from different places in ore-channels, most of the workings resembling huge rabbit warrens with an occasional cave and burrows leading from them. The widest make of ore worked has a width of 15 ft., with no walls showing on either side, but in most cases the ore-bodies worked were from 4 to 6 ft. in width. According to the official records at the Arltunga government battery, the first parcel dealt with from the White Range was in 1898, and the last in August, 1913. Those from White's Blocks totalled 7,863 tons, the value of the gold recovered by amalgamation and cyaniding the sandy tailing was £44,780, an average result of £5 18s. 6d. per ton, equal to a return of 1½ oz. of fine gold. Only the sand and not the slime was cyanided, the recoverable value from such source being about one-fifth of the total. The value of the battery gold ranged from £3 8s. 3d. to £3 16s. 3d. per oz., the average being £3 12s. In the year 1914–15, 110 tons of this slime at this mill was treated by the government for a return from cyaniding of gold to the value of £402. The best parcel from the White Range was

ore of 1776 tons [illegible] at the Excelsior workings, which returned gold to the value of £3,548 12s. 6d. The values of [illegible] were very consistent, the last series totalling 627 tons for a return in value of £3,549. According to earlier expert reports, the proportion of material treated to that mined was from one-fourth to one-third, so that the gold recovered from the workings would average from 7 to 9½ dwt. per ton of material raised.

In close vicinity to the Blocks are two government wells, one 70 ft. in depth, with a fresh water supply of 150 gallons per day, and the other 150 ft. deep with a supply of 250 gallons. The other wells, all of which are government, within a radius of 5 miles of the properties are Police Camp well with a supply of 3,000 gallons; Paddy's Hole well, 1,000 gallons; Cross Road well, 250 gallons; Battery well, 5,000; and Whipe-Out well, 50 gallons of fresh water per day. The supply from these wells would be insufficient for an undertaking of any magnitude, and the only way of obtaining an ample supply, so far as can be foreseen, is by excavating a reservoir of large capacity in a clay flat near the Habe River, about five miles distant. There is only little gum and mulga in the creeks, the nearest mine timber of any importance being on the Habe River, and the quantity there is limited. Transport is by camel and horse team from Oodnadatta, the most direct route being from Deep Well, past Williams' Well (a stage of 70 miles, excepting shortly after rains), where the Alice Springs-Arltunga Road is met with. The climate is very healthy, with cold days and nights in the winter and hot days with cool nights in the summer. The rainfall averages about ten inches annually, falling mostly in the summer months, although good winter rains up to four inches are often experienced. There is very little, if any, suitable mine labour in the district, practically all the labour required for any mining operations having to be brought from south.

The gold-bearing formations cannot be termed lodes or reefs, and the only expression that conveys any idea of their character is ore-channels. Only the known richer places in them have been worked, but even so, should they go down, as they give every promise of doing, and retain their gold contents, the properties, when opened up in a systematic manner, may be of great value. Some of the formations can be easily and cheaply tested by means of tunnels from the eastern base of the range, one of the best sites for an adit being below the main workings of the Excelsior, where that formation could be driven into at a depth of 250 ft. below the workings and cross-cut by tunnelling a distance of 850 ft. Only in one of the workings was there any mineral detrimental to cyaniding, this being a small seam of copper ore containing arsenic in an underlie shaft on the Excelsior.

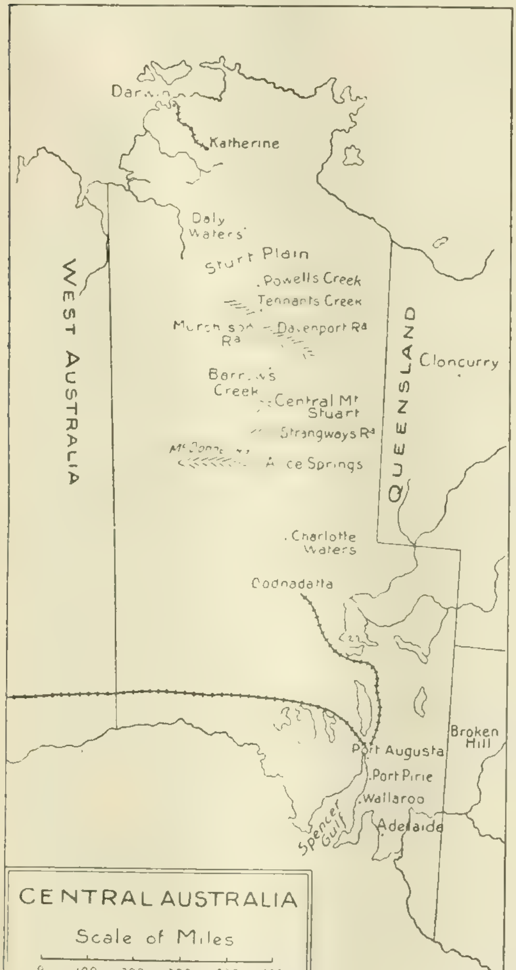
Twelve miles north from Alice Springs telegraph station the overland track passes through the ranges to an extensive, well-grassed plateau called Burt's Plain, having a gradual inland fall from 2,600 to 2,200 ft. above sea-level. For a distance of 40 miles the ranges are in close proximity to the east, but recede rapidly to the westward. Of this eastern branch of the ranges, known as the Strangways Range, Mr. Brown, the geologist, reports that the rocks consist of granite, syenite, diorite, and schistose granitic rocks with quartz reefs, and are favourable to the occurrence of gold. This definition also accurately describes and is applicable to the country passed over between Winnecke's goldfield and Alice Springs. From this range until the Buxton Ranges are reached only recent formation at a mean elevation of 2,200 ft. is met with, except at the low Hann Range, where primary rocks outcrop. In the Buxton Ranges are fair-sized areas of granitic country with slate carrying quartz, and ironstone reefs well worthy of being prospected for tin and gold. Galena was found at their western extremity. Thence along the track, passing Central Mount Stuart, the south-easterly end of the John Range, to the country near Barrow Creek, any rock formation that may exist is covered with recent deposits. The only information procurable of this high belt of country to the west is that contained in a government prospecting report of the party's rushing, in the year 1906, over then drought-stricken country in a futile attempt to reach Tanami. According to this record the mineral possibilities of the John Range, where the party saw a little copper ore and raised a colour of reef gold, appear to be fairly good, especially for gold, tin, and copper.

The few low ranges about and up to 30 miles north of Barrow Creek trend in an easterly and westerly direction. Nearly all are capped with quartzite, sandstone, and conglomerate overlying metamorphic granite and sandstone with slaty rocks and quartz reefs, which outcrop on their lower slopes. In the year 1919 an aboriginal discovered wolfram at the foot of the most southern one, called Foster's Range, and a ton or so of that ore was obtained and sent away. All the country then on to the outliers of the Davenport Range is recent and Tertiary, and of an average height of 1,500 ft. above sea-level.

The Davenport Range is one of the two most extensive geological features between Oodnadatta and Darwin. With the north-westerly extension, called the Murchison, their length is 150 miles with a breadth of 30 miles. The overland telegraph line and track crosses the extreme westerly end, where the ranges are low and narrow, and continues northerly for 40 miles at a few miles distance from the western margin of the Murchison Range. The prevailing rocks are sandstone, quartzite, conglomerate, and grit, which have formed flat-topped ranges of uniform heights to an altitude of 400 ft. above the surrounding country. Through denudation of this formation the older metalliferous rocks are exposed over large areas, the same agency having produced the numerous long, wide valleys that now exist between the ranges. During the years 1898–9 a party under the leadership of Mr. Allan Davidson prospected these ranges for gold. They discovered several auriferous areas, some fairly extensive, and put down shallow shafts on a few of the most promising gold-bearing reefs located, which were found to be too low a grade to be profitably worked under then existing conditions. As their main object was the discovery of rich gold reefs, only a little alluvial gold was sought for and obtained. The party also located some copper-bearing deposits, galena, common opal, and a mineral that was subsequently proved to be wolfram, when one of the party, subsidized by the government, revisited in 1914 the place of discovery. This field is now called Hatches Creek wolfram field, although it was about a year later before any mining work was done there.

Hatches Creek field is situated about 700 miles

from each of the termini of railway lines at Oodnadatta and Katherine respectively and 350 miles from the Duchess-Sullivan Creek railway, near Cloncurry, Queensland. The latter route is through waterless desert country for most of the way, but on account of the great disparity of distances it has, during the past three years, been used in preference to the Oodnadatta track. The wolfram belt runs in a northerly and southerly direction for a distance of 5 miles, its maximum width of 2 miles being at its southern end. Within this area are numerous wolfram-bearing quartz reefs, veins, and



short, irregular shoots from 1 in. to 4½ ft. in width with varying lengths up to 300 ft. The strike of the reefs is mainly in conformity with the country, and has a steep westerly dip. The enclosing rocks are metamorphic sandstone, quartzite, conglomerate, slate, and schistose granitic rocks, the two latter being principally at the northern end, where scheelite is the predominant mineral found, and where, in close proximity, there is a small auriferous area discovered by Mr. Davidson's party. The tungsten ores are very irregularly distributed throughout the matrix, being chiefly found in patches and shoots with stretches of barren material intervening; still in some of the reefs a run of fair grade ore is met with. Oxide of iron, a little copper, and bismuth, are associated with the wolfram at the southern end of the field. Mining operations, more or less of a perfunctory nature, were profitably carried out on this field from the year 1915 up to when the price of wolfram slumped early last year. By that time the deepest working was 117 ft. from the surface. Only a few men, and those at a high rate of wages, or if preferred by the employee, on a good term of tribute, could be induced to go there. At no time were there more than fifty Europeans on the field, and at the time of the writer's visit in September last they numbered only sixteen, the majority of whom were about to leave. The output of the field to date is about 250 tons of 66% wolfram ore and 25 tons of scheelite at a little higher percentage, all, with the exception of some alluvial, obtained by burning and dollying the material mined.

Another important wolfram field, known as Wauchope Creek, is also situated in the Davenport Range, about 60 miles N.N.W. from Hatches Creek, 6 miles easterly from the overland telegraph line and track and nearly midway between Oodnadatta and Katherine. In the year 1917 an aboriginal engaged in horse hunting discovered wolfram there, and shortly afterwards the whole of the wolfram-bearing area comprising a small parcel of land 50 by 20 chains was pegged out in small holdings. These latter are in a small metamorphic sandstone and slate belt about 3 miles in length and from a chain to 20 chains in width, trending N.N.W. and S.S.E., bounded on the east by a table-topped range of desert sandstone, and west by a line of low hills and ridges of quartzite bordering on scrubby plain country lying immediately to the south-west. Within this belt at its central and widest part are a series of wolfram-bearing quartz reefs and leaders from 1 in. to 2 ft. in width outcropping for distances up to 800 ft. Their uniformity is remarkable, and the majority of them trend with the country and have a flattish dip to the north-east, gradually becoming steeper so far as worked down. Wolfram ore of good grade was obtained in places along quite a dozen of the principal reefs and for long distances in some of them. Mining operations carried out are of the nature of irregular open-cuts, very little of a systematic nature having been done. The deepest of the few shafts sunk is only 40 ft. from the surface. Where rich stone was showing on the surface it was simply rooted out, and when such a patch became poorer, another was found and dug into. The richness of some of these was phenomenal, men on tribute obtaining as much as 8 tons of clean wolfram for three or four weeks' work. As at Hatches Creek, operations were handicapped through want of labour. At no time were there more than 26 Europeans on the field, all but five or six of them being wage and tribute men. Want of water was also a drawback, the nearest permanent water supply being 16 miles away; moreover, all transport was by camel team to and from Oodnadatta, 600 miles distant. Notwithstanding these disadvantages and the occurrence of a four months' strike of wage and tribute men, the claim-holders made net profits of many thousands of pounds out of wolfram obtained from their mines during the short period of work. At the time of the author's re-visiting the locality in September last, the holdings were under exemption from labour conditions, and only

two Europeans were there. Some nice wolfram was then showing on the face at different workings. So far the field has proved to be exceptionally rich in wolfram, and there is every promise of continuance and the reefs living to great depths. The output to date is approximately 237 tons of 68% wolfram ore, all perfectly free from any detrimental substance, and obtained, except when mined in solid lumps and alluvial, by burning and dollying wolfram-bearing quartz. Very recently the majority of these mine holdings, including the principal leases, have been acquired by an Adelaide company with £12,000 working capital.

Prior to Mr. Davidson's party, no prospecting work was carried out in these ranges, and the little that was done subsequently was solely for wolfram, a small quantity of that mineral being found a mile south from Woodineera waterhole in the Frew River, 40 miles to the north of Hatches Creek, at the head of Lennie Creek, mid-way between the two fields, and in some quartz veins and alluvial at the Marbles, 8 miles northerly from Wauchope. Although areas of granite country have the appearance of being stanniferous, the only discovery reported was of a few ounces of black tin ore from gully wash near Wauchope Creek.

Since the author's course was along the ranges from Hatches Creek to Wauchope Creek, mostly through trackless country, the Kurrundie gold reefs were not visited. These are close to the Hatches Creek-Tennant's Creek track, and, according to Mr. Davidson's report, are large, low-grade propositions payable to work under favourable conditions. Since his party left nothing further has been done there, although from time to time the areas have been taken up solely for speculative purposes.

Along the overland track, after leaving the Davenport Ranges, past Kelly's well (1,100 ft. above sea-level) to the McDouall Ranges near Tennant's Creek, undulating sandy country is passed over for most of the way, the older formations of metamorphic sandstone, quartzite, and granitic rocks with quartz veins being only met with at the westerly outliers of the Murchison Range. The McDouall Ranges are actually a continuation of and a westerly branch of the Murchison Range. No eruptive rock was seen by the writer in passing through them, but in every other respect they appear to be of similar formation ; their maximum height does not exceed 1,600 ft. above sea-level.

After leaving Tennant's Creek there is no metalliferous country until the Marranboy tin belts are reached. Patches of broken tableland, continuations of similar higher formations to the westward, are between Attack and Woodforde Creeks on the Tennant's-Powell stage, and also between Powell's Creek and Newcastle Plains ; the rocks are desert sandstone, quartzite, and conglomerate, lying very flat. At Banka Banka station, 20 miles from the western edge of the Barkly Tablelands, there is some coarse, acid, grey granite. A little opalized quartz was observed between Banka Banka station and Helena Springs, where opal was discovered. Outcrops of acid, grey granite, and coarse conglomerate occur between Sturt's Plain and Daly Waters. From then on to the stanniferous country mentioned, recent and Tertiary formations overlie limestone, as in the Barkly Tableland, but nowhere in this long stretch of country—some 400 miles—is there any likelihood of a mineral find being made.

From Marranboy the author travelled via Maude Creek old gold and copper diggings, 40 miles to Katherine, thence by train to Darwin. As these two mining fields are well within the coastal district, and, with others similarly situated, have been described by geologists and other officials, and as the conditions pertaining to such are totally dissimilar to those inland, it is not necessary to refer to them here.

The metalliferous areas described and commented on in this article are, with the exception of Tanami and the Petermann Range—where a few colours of gold were found—all those known outside the territorial coastal belt. They are on these uplands extending from the 19° 30′ to the 24° parallel of south latitude, and from 200 to 300 miles from the border line between the Northern Territory and Queensland. Only small portions of this huge area of country have been prospected, and that mostly in a haphazard manner. Past and existing conditions and circumstances offer little, if any, inducement to the prospector, and the great distances from rail and centres of population, combined with the costly, slow, and unreliable transport facilities, practically prohibit the development of any of the known mines, even by companies with a large working capital.

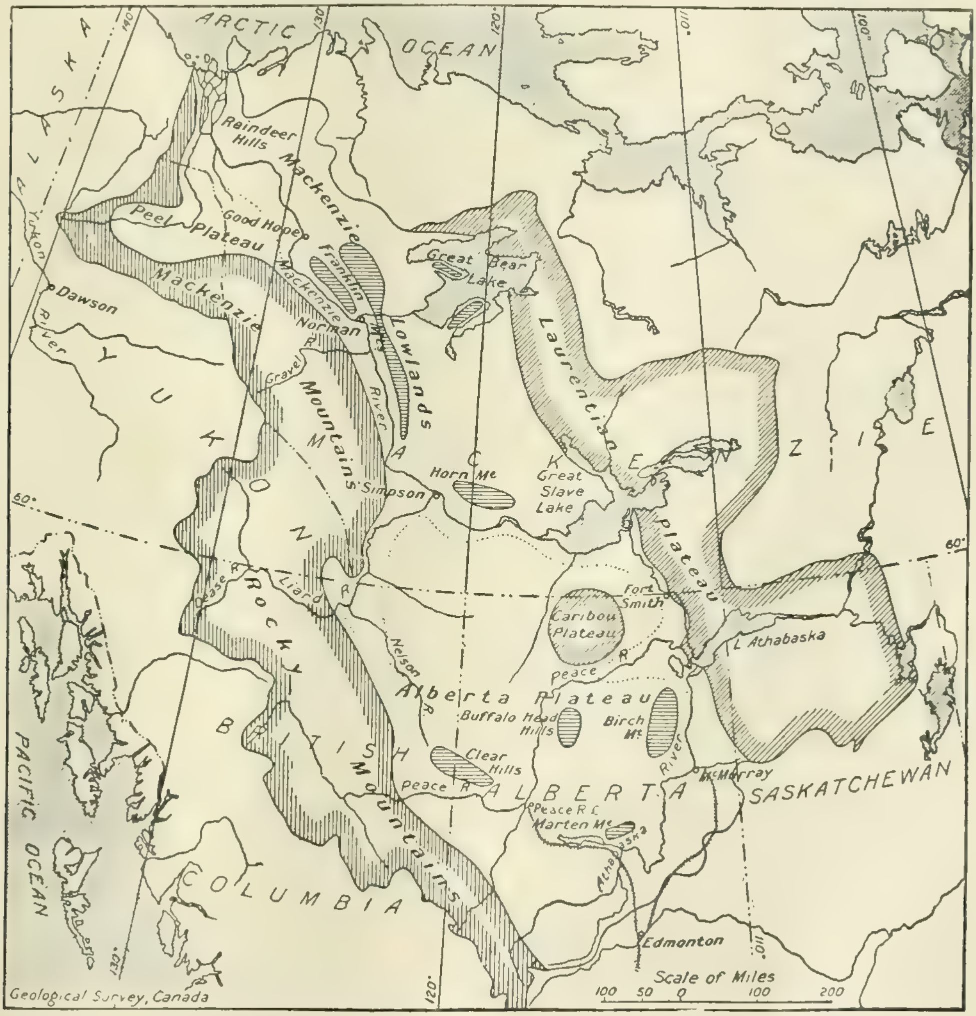
The climate over the whole area is very healthy, with hot dry heat in summer, cool days and cold and often frosty nights in the winter. The average annual rainfall, which is somewhat irregular, is about 10 in., falling in heavy showers in the summer, the winter rains being of a drizzly nature, accompanied by cold easterly winds. There is nothing in the nature of the climate to retard European labour efficiency to any appreciable extent. In no sense is the country tropical or semi-tropical, and malarial and other enervating disorders prevalent on the coastal mining fields are unknown. Timber for mining purposes is scarce over all the metalliferous areas, the trees on the ranges and hills being hollow, stunted, and scattered, and only fit for firewood. Good mine timbers of mulga, bloodwood, and gum are obtainable in limited quantities in the valleys of creeks and so-called rivers, and from the surrounding country. Water is scarce throughout the Macdonnell Ranges. There are a few large waterholes and springs, and a limited supply is obtainable by sinking in some of the creeks to depths up to 100 ft. For any big mining undertaking, however, water would probably have to be stored in dams or reservoirs. In the Davenport Ranges there are numerous waterholes, some very long and deep and practically permanent. Along the telegraph line north from Alice Springs (which is a misnomer, as there are no springs there) fair supplies of water have been struck at shallow depths in some of the government wells. It would therefore appear that any water difficulty would not be of a serious nature, and could be easily overcome by conservation.

As regards a route for the proposed north-south continental railway, the direct route to connect the present termini—Oodnadatta and Katherine—is via Arltunga through the Hart's Range mica field, not anywhere near Alice Springs, as most people seem to think, then on past Wauchope Creek wolfram field. For engineering and other reasons, however, a deviation from Arltunga in the direction of Hatches Creek, and then through the north-western portion of the Barkly Tablelands may be preferable.

OIL PROSPECTING IN THE MACKENZIE RIVER DISTRICT

The *Canadian Mining Journal* for May 6 prints an article by E. M. Kindle, of the Canadian Geological Survey, containing a number of suggestions to oil prospectors in the Mackenzie River Valley. The opening of navigation in the Mackenzie River basin this season will probably witness a northern migration of oil prospectors, unprecedented in western Canada. A large proportion of those who are likely to make the long journey to the new oil-field below Norman on the Lower Mackenzie will probably have little or no knowledge of the conditions under which they must live in this region. A few suggestions and some bits of geographical information from one who has spent two seasons in the Mackenzie Valley will be helpful to many who go into the great Northland for the first time, and also to many others who do not.

While prospectors will find a genial summer climate, they will need to provide with some care for the sub-Arctic winter conditions which follow the summers. One of the most important of these provisions for winter is a cabin. It should be clearly understood that there are no road houses or other establishments furnishing public accommodation anywhere in the Mackenzie Valley. The environment of the North exercises a selective influence on the human as it does on the other kinds of animals found within its bounds. The man who lives in the North as a trapper must in winter be able to visit his traps and sleep in the open at a temperature of 60° below zero. Losing a trail in the spruce forests is likely to mean freezing in winter and starvation in summer. He must have a keen sense of direction and the ability to estimate accurately the limitations of his canoe. An error in estimating the hazard of a rapid or the strength of a gale results in his elimination from the field of adjustment to northern conditions. So the white men whom one meets on the northern rivers and lakes represent as a rule a selected group of men who have proved themselves fit to cope with conditions which quickly weed out the human weaklings.



MAP GIVING AN OUTLINE OF THE PHYSIOGRAPHY OF THE MACKENZIE RIVER BASIN.

Edmonton is the logical place for outfitting if one wishes the advantages of large and well-stocked stores, but most of the provisions required for an expedition into the North-West Territories can be obtained either at Peace River Crossing or McMurray. At one or the other of these points the north-bound traveller takes final leave of railways and hotels and must be prepared to depend entirely on his own resources. After provisions the next most important items for the outfit are one or two heavy woollen blankets or some form of sleeping-bag and a mosquito-proof tent. No experienced man will neglect the latter, and the nearly equally important items of light-canvas gloves and head nets in outfitting for any part of the northern wilderness. He who neglects these precautions against the universal mosquito pest of the North-West will have good cause to regret his negligence and probably decide that he would have enjoyed just as much a sojourn in the super-heated climate of tradition.

One of the things which should be included in the outfit of the prospector going into the Mackenzie basin in a geological map of the region. This may be obtained by writing the Director of the Canadian Geological Survey at Ottawa for a copy of Memoir 108. Another small but important item of the outfit is a pocket compass. The north-bound traveller may be reminded here that his compass readings require correction as he journeys north in somewhat the same way as does his watch on a transcontinental trip. At Fort Smith the needle points not even approximately north, but 33° 23′ east of north. At Fort Norman the declination east is between 41 and 42 degrees.

Any approach by rail to the Peace or Athabasca rivers, which are the great waterways leading toward Great Slave and the Mackenzie, must be through the city of Edmonton. This thriving modern city was a very few years ago only an obscure trading-post of the Hudson Bay Co. on the Saskatchewan River. A railroad was completed a few years ago from Edmonton to Peace River Crossing on the Peace River, which is about 312 miles north-west of Edmonton. Another railroad extends north from Edmonton via Lac La Biche to the head of navigation on the Clearwater River. This railway ends near McMurray ; from that point to the Arctic coast steamer navigation on the Mackenzie is interrupted at but one point, the rapids at Fort Smith, where there is a portage of 16 miles. It should be noted, however, that while the latter route is the most direct the service beyond Lac La Biche is frequently discontinued for considerable periods because of the condition of the road bed. The Peace River route is longer and involves a four-mile portage at the Vermillion chutes which the McMurray route avoids, but the railway transportation is more dependable. The distance from the end of the railroad at Peace River Crossing to the oil well is about 1,500 miles, and from McMurray about 1,200 miles. Telegraph service extends to Peace River Crossing and to McMurray, but not beyond.

Two lines of steamers have for a number of years been engaged every summer in bringing out the winter catch of fur and taking in the yearly consignment of supplies to the trading posts which are located from 100 to 200 miles apart throughout the Mackenzie River system. A third line began operations in 1919. These steamers make only a single round-trip to the most northerly posts. Two or more trips are ordinarily made to points on the Upper Mackenzie. The companies operating steamers on the Mackenzie in 1920 were the Hudson's Bay Co. and the Northern Trading Co. Both of these companies have offices in Edmonton. The round-trip steamer rate quoted by one of the transport companies this season from McMurray to the oil well, including meals and berth, is $300. A freight rate which has been quoted between these points (north) is $10·25 per 100lb. During the winter season the only communication between the Mackenzie Valley and the outside world is maintained by dog sledges or carioles which carry the mails in and out of the Mackenzie Valley once a month. Only first-class mail, however, is carried on these. It may well be understood that to the inhabitants of the Mackenzie Valley the great seasonal events of the year are the opening and closing of navigation on the waterways of the basin.

The ice of Great Slave Lake blocks the navigation of the Mackenzie River for nearly a month after the great river is free of ice. Owing to this fact navigation on the Mackenzie is limited to about 3½ months. The record of the ice break-up at Rae on Great Slave Lake entered in the Hudson's Bay Company journals and published by Russell shows the break-up during 6 years (1857-9 and 1883-5) to have ranged from May 30 to June 23. The general direction of the wind in spring, however, drives the ice toward the southern shore so that steamers seldom venture into the lake before the first of July.

The Mackenzie at Simpson, which is near latitude 62°, opens between May 4 to May 20, averaging from the 10th to the 15th, according to Captain Mills, who has spent several years at Simpson and has run steamers on all of the navigable waters of the Mackenzie basin. Because of nearly dead water in the Mackenzie for a long distance, the head of the river opens 2½ or 3 weeks later than at Simpson. The opening of Great Slave Lake generally occurs, according to Captain Mills, between June 16 and July 2, or six weeks later than the Mackenzie below Simpson.

Fur constitutes the sole commercial product of the country, and prospective travellers in the Mackenzie Valley may be reminded that the transport companies were established solely for the purpose of getting the fur out of the country, and a limited amount of provisions in each season to the trading posts, not for the accommodation of the travelling public.

The approximate distances between the trading posts on the Mackenzie River system north of the end of the railroad at McMurray are indicated in the following table :—

From McMurray to	Miles.
Fort Chipewyan	190
Fort Fitzgerald	280
Fort Smith	296
Fort Resolution	490
Fort Hay River	570
Fort Providence	660
Fort Simpson	835
Fort Wrigley	995
Fort Norman	1,155
Oil Well	1,201
Fort Good Hope	1,330
Fort Arctic Red River	1,570
Fort McPherson	1,635
Fort Scenic	1,735

A company has been organized which proposes to build a railway around the Slave River rapids between Fort Smith and Fitzgerald. At present,

however, all freight must be transported across the 16 miles between these two points by wagon or tractor. Steamers will leave Fort Smith for the first trip down the Mackenzie about June 24. Departure from the same point on the second trip will be about July 26.

The Mounted Police have the authority to turn back any individual whom they consider for physical or other reason unfit for the trip. The inspector at Fort Fitzgerald, which must be passed by all persons entering the Mackenzie Valley, is required to take certain personal information regarding each individual going beyond that point. This interview may include a request for evidence that arrangements have been made with some power-boat for return transport or that a contract for a year's supply of provisions has been secured. It is necessary to begin the return trip from Norman not later than September 28 if a winter sojourn is not planned.

It is reported that aeroplane service to the new oil district will be available for those who do not mind paying $1,000 for the round-trip. The Imperial Oil Company is preparing to use planes for the purpose of taking in its own employees.

It is probable that many persons wishing to go north this season will find it impossible to secure accommodation on the steamers. Such persons will, however, find it possible to make the trip north by canoe, and to make very good time with the aid of the river current. The return trip, of course, cannot profitably be made in this way, since the journey is up stream. A man skilful with tools can build his own boat on the river bank at Peace River Crossing.

In the northern latitude where daylight lasts about 24 hours in June it is feasible for large canoes to travel day and night if the party wishes to speed up. The mosquitoes are less active during the cool nights, which is often another incentive to night travel. The writer has covered the 200 miles stretch between Fort Smith and Resolution by day and night travel in 2½ days. This method for short periods involves no hardship, if the night is divided into two or more watches with only one man at the paddle, while the others sleep or study astronomy from the bottom of the canoe. There are only two points on the entire Mackenzie River where the canoeman needs any special advice in regard to avoiding rapids. One of these is opposite the site of Old Fort Wrigley. Here the river splits on a rocky island. Loaded canoes and scows should take the west channel. The narrow eastern channel is rather swift water. The other locality is the Sans Sault rapids. Here also the canoeman should take the west side of the river keeping near the shore. The Vermillion chutes and the Smith rapids on the Slave are always portaged.

The Mackenzie basin embraces a vast area representing some 680,000 square miles of territory in North West Canada. Extending over nearly 17° of latitude it necessarily includes a considerable variety of physiography. A great central plain bordered on the east by the Laurentian plateau and on the west by the Rocky mountains and their northern extension, the Mackenzie Mountains, represent the major physiographic features of the region. The mileage of the new oil well is equivalent to the distance from Ottawa to South Florida. Since there are no roads and very few trails, travel in the Mackenzie Valley is strictly limited to the waterways. Everywhere dense forests of spruce and poplar, muskeg, or small lakes cover the lowlands near the rivers. These generally render travel across country nearly impossible or extremely slow. In all the 1,200 mile stretch of lake and river between the end of steel at McMurray and the oil well, the traveller will see only eight or ten Indian villages, with two or three fur-trading stores at each to interrupt the virgin forest. The total population of the entire Mackenzie district will probably not exceed 5,000. Probably less than 150 of these are whites, the remainder being Indians, except 200 or 300 Esquimaux.

Oil in Saskatchewan.—The throwing open of the Pasquia Hills Forest Reserve for oil prospecting under the recent amendments to the Dominion Oil Regulations, has drawn attention once more to this potential oil region. To readers of the MAGAZINE its position is best indicated by recording that it is about 40 miles from The Pas over the Saskatchewan-Manitoba border. The presence of large bodies of oil shales in these hills has long been known. In the course of his report to the Geological Survey on the basins of the Nelson and Churchill Rivers, William McInnes made several references to these shales. His report, which was written in 1911, was published two years later as Memoir No. 30. The *Canadian Mining Journal* for April 8 gives extracts from this report.

According to Mr. McInnes the overlap of the Cretaceous sediments is marked for a hundred miles west of Lake Winnipegosis by the bold escarpment of the Porcupine and Pasquia Hills, and farther west by the equally high but gently sloping Wapawekka Hills. A partial section of Cretaceous rocks making up the Pasquia Hills was seen where the rocks are exposed in gullies worn by streams descending these northerly facing slopes. An estimated section along these gullies, compiled mainly from exposures observed in the trench worn by Nabi River, is as follows, in ascending order :—

35 ft. to 40 ft. ; thick bedded, soft grey arenaceous oil-shale or thin bedded sandstone, holding the remains of fishes.

6 in. ; compact impure limestone.

120 ft. or more ; soft, fissile, light grey (almost black when wet) oil-shales, holding the comminuted remains of fishes and many foraminifera.

15 ft. ; clay iron-stone in beds 6 in. to 1 ft. in thickness, divided by thin partings of shale.

10 ft. ; soft fissile, grey shale that seems to be similar to the oil-shales below.

The whole is overlain, to the surface, by 10 ft. or more of boulder clay containing many boulders of limestone and a few of Pre-Cambrian gneiss and granite.

The fossils from the section given above were probably of Niobrara age. The thickness of the Niobrara in Manitoba has been computed to be from 130 to 200 ft., comprising calcareous shales, which pass downwards into the shale of the Benton.

The base of the section given above lies at a height of 400 ft. or more above the bed of the Carrot River, where, at the rapid above the Red Earth Indian reserve, ledges are exposed that are thought to represent the Dakota division of the upper Cretaceous. They consist of 5 ft. of very soft quartzose sandstone deeply stained with iron oxide, lying in undisturbed heavy beds that show false-bedding, and hold nodules and irregular masses of iron pyrites. In places the sandstone becomes a fine conglomerate,

in certain layers with pebbles of gneiss and other rocks, and in places it contains carbonaceous material resembling the comminuted remains of plants. The soft sandstone is overlain by hard, white quartz sandstone with distinctly red-purple tinge, which is strongly ripple-marked on some surfaces.

Fifty miles farther up the Carrot River from the rapid at which the sandstones are exposed, and at an elevation of about 400 ft. above that point, grey oil-shales similar to those of the Pasquia Hills section form the low scarped banks of the river. There is thus an interval of 400 ft. or more between the observed beds of Dakota sandstone and those of Niobrara shale. A great part of this interval, which on the side of the Pasquia Hills and in the valley of the Carrot river is covered by deposits of boulder clay and by later stratified sands and clays, is without doubt occupied by the shales of the Benton. Shales considered to be of Benton age which, from their relative elevation, would fall into this gap, were observed by Mr. J. B. Tyrrell in the bed of the Saskatchewan below Birch islands.

The Carrot river, which joins the Saskatchewan two miles above The Pas flows past the Red Earth Indian reserve. From the crossing of the second base line westerly, the steeply sloping front of the Pasquia Hills rises from the flat land to the south of the river all along. The hills rise to a height of about 1,600 ft. above the valley or 2,500 ft. above the sea. The hills are made up for the most part of Cretaceous sediments, though the base is probably formed of Palæozoic beds and the summit is covered by varying thickness of boulder clay.

The only exposures of rock in place seen in the Pasquia Hills by Mr. McInnes were found in the gulches eroded by streams flowing down the hill-slopes. They consist for the most part of soft, grey, fissile shales that contain a considerable amount of bituminous matter, enough to cause them to burn freely, with the emission of a strong odour of petroleum when heated in the camp fire. The best exposures were found in the valley of the Nabi river, where 140 ft. or more of thick-bedded sandstone, holding the remains of fishes, bivalves, and foraminifera, are exposed in cliffs along the river; the species are characteristic of the Niobrara division of the Cretaceous.

Altogether more than 40 square miles of territory in the Pasquia Hills have been staked since December last, when the new oil regulations came into force. Syndicates have been formed and it is understood that several drills will be on the spot at an early date. A miniature boom is, in fact, being staged, and local hopes of a future producing oil-field are high. Expeditions have been sent out by business men from The Pas, while interests in cities in western Canada have put up money for exploration work. Many samples of shale have been brought into The Pas, which when lighted will burn freely. Samples of paraffin wax and fossilized remains of fish are also on view. The break-up of frost has interfered with traffic between The Pas and the Pasquia Hills for a time, and it is unlikely that any further parties will venture out until open water, when it is anticipated there will be a big rush to take up sections. The Pasquia Hills are reached in the winter time by horse team and dog sleigh, and in the summer there is a water route running into the foothills, from whence the best method of travelling will be by pack horses. Since the above was written, many parties have gone into the region.

Zinc Determination.—In the *Journal* of the Society of Chemical Industry for May 31, E. Olivier, writing from the Central Laboratory of the Vieille Montagne Company, discusses the determination of zinc by the potassium ferrocyanide method. The determination of the zinc content of Australian concentrates is usually carried out volumetrically, either by the so-called American method (the potassium ferrocyanide method) or by the Schaffner method (titration of the ammoniacal solution with sodium sulphide); this last method is also sometimes termed the Vieille Montagne method (see Frevet, *Bull. Soc. Chim. Belg.*, 1919, 28, 351). In the American method, as usually carried out, the ore or concentrate is decomposed by means of nitric acid and potassium chlorate, the mixture evaporated to dryness, the residue boiled with ammonia and ammonium chloride solution, and the filtrate acidified; the copper is removed by means of lead foil, the liquid is neutralized with ammonia, a solution of potassium hydrogen tartate and ferric chloride is added, the solution heated to about 75° C., and titrated with standard potassium ferrocyanide solution in presence of ammonia until a spot test with acetic acid shows a blue coloration. The method used for preparing the solution for analysis results in the extraction of the zinc, together with the copper, cadmium, calcium, and magnesium, and part of the lead, iron, and manganese. Of these elements only the zinc, copper, cadmium, and manganese are precipitated by the ferrocyanide, and only the copper is removed prior to the titration, so that the cadmium and manganese present are returned as zinc. While the amount of cadmium present in the concentrates is usually so small as to be negligible (it averages about 0·1%), this is not so in the case of manganese, which may be present to the extent of considerably more than 1%, and so result in a high figure being returned for zinc. In one case, for example, the author found 1·16% of manganese (as Mn_3O_4) in the zinc solution before titration. That amounts of manganese such as are found in concentrates vitiate the titration is shown by experiments in which manganese corresponding to 2% and 4% respectively of Mn_3O_4 was added to solutions of known zinc content; on titration of these solutions, 0·8% and 2·3% of zinc in excess of the quantity present was indicated. To separate the manganese completely from the solution, a few cubic centimetres of hydrogen peroxide are added to the mixture of ammonium chloride solution and ammonia used to treat the residue resulting from the decomposition of the ore; this renders the manganese insoluble, and the results obtained agree closely with those found by the Schaffner method. When the percentage of manganese present is small (for instance 0·25%) the results obtained by the two methods (without the use of hydrogen peroxide) agree within about 0·1%, but in most cases manganese will be present in amounts sufficiently great to necessitate the use of hydrogen peroxide. The American method has another disadvantage, especially where a large number of titrations have to be made daily, namely, the titration is carried out in hot solutions; this is necessary in order to obtain complete precipitation of the zinc ferrocyanide in a dense, gelatinous form. Further, the blue coloration produced in the spot test is not entirely satisfactory, since although the reaction is sensitive the colour is not always very distinct in presence of coloured

ferrocyanides and the intensity of the colour is not appreciably increased with increasing amounts of potassium ferrocyanide. In the author's opinion the Schaffner method is preferable to the American method, in view of the above facts, and also having in mind the fact that the zinc is precipitated as colourless sulphide, which affords a ready indication of its freedom from other metallic sulphides. The only other colourless insoluble sulphide known is the double sulphide of zinc and cadmium, discovered by the author in 1886, but the error arising from this source is negligible since, as already pointed out, zinc ores contain very little cadmium, and, moreover, the greater part of the cadmium is separated as sulphide together with the lead and copper.

Solution and Deposition of Iron.—The *Journal* of the Society of Chemical Industry for May 16 contains a paper by J. Haworth and J. Evans entitled "The Ochre Streams of the Valleys of the Don and Loxley, South Yorkshire". The paper dealt primarily with questions of water supply, but it is of interest to geologists also, as it refers to bacterial action in depositing iron.

The authors define ochre waters as natural waters in which salts of iron occur in solution. In most cases such waters deposit iron oxide or ochre on the banks and bed of the stream. They may be conveniently sub-divided as: (1) Chalybeate waters, which occur either as waters containing carbon dioxide and iron bicarbonate, together with other salts, or as saline acidulous chalybeates containing chiefly sodium sulphate and iron bicarbonate; and (2) waters containing chiefly sulphates of iron. The chalybeate waters seldom contain large quantities of iron (8 to 15 parts per 100,000). They emanate from strata containing iron in the form of carbonate, which in the presence of carbon dioxide forms the soluble bicarbonate. Waters containing sulphates of iron are frequently found in all districts where coal workings exist or where outcrops of the coal measures occur. The streams in valleys draining areas in which coal measures are exposed frequently bear marked indications of the presence of iron salts by the brown and red deposits of ochre on the beds of the streams and by the brown colour of the water.

The River Loxley is a tributary of the Don, and the watersheds are divided by a precipitous ridge in which outcrops of the lower coal measures occur at numerous points and are exposed. Beneath the lower coal measures beds of ganister and fireclay occur. These are worked at numerous points on both sides of the ridge, the products being largely used in the Sheffield industries. The mining operations consist usually of driving levels or adits into sides of the valleys at different levels where the outcrops occur, and water drains from these forming streams which flow down to the river. There are also other streams flowing from the slopes of the valley, but a casual observation shows that the streams from the mines or ganister pits all contain salts of iron and deposited ochre, whereas the remaining streams contain no iron. The physical appearance of the ochre streams is striking. In some cases the water is clear but coloured, the colour varying from pale yellow to a deep reddish-brown; in other cases the water is turbid through the presence of iron hydroxide, but in all cases heavy deposits of iron hydroxide or basic iron sulphate are present. The source of iron salts is without doubt iron pyrites between the layers of the coal strata. Specimens of the shale and coal when first exposed show distinct layers of pyrites in the course of oxidation; in splitting the layers perfect crystals of transparent calcium sulphate in the form of selenite, $CaSO_4, 2H_2O$, may be observed. This substance also finds its way into the water. The waters issuing from the mines contain ferrous and ferric sulphates, and free sulphuric acid, the primary oxidation products of pyrites. In the streams further reactions occur producing the heavy red deposits which consist of ferric oxide and basic ferric sulphates. In some cases the banks consist of this deposited ochre for several inches in depth.

The ochre deposits have their origin in several ways: (1) Direct oxidation and the production of ferric hydroxide; (2) alkaline surface waters joining the stream; (3) the action of iron bacteria which grow profusely in such waters. The first two methods of deposition are purely chemical; the third is of considerable interest. Water containing iron salts, even in very minute quantities, forms a very suitable medium for the growth of the organisms commonly referred to as "iron bacteria"; two common varieties of these are *Crenothrix polyspera* and *Leptothrix ochraceæ*. As little as one part of iron in 2 to 3 millions of water is sufficient to permit the development of these organisms. The organisms decompose the salts of iron, depositing the iron in the form of ferric oxide, and liberating acid. In the case of ochre streams such as those under consideration the organisms deposit the ferric oxide and the streams become acid. The organisms have very high chemical energy and are able to oxidize ferrous salts many times the weight of their own cells. They are remarkable by reason of the fact that their existence is maintained largely by inorganic salts and the presence of only minute quantities of organic matter is necessary. In the case of the two rivers mentioned the usual flora and fauna are entirely absent.

Rod Grinding Mills.—In the *Engineering and Mining Journal* for May 28, E. H. Robie discusses the development of the rod-mill, that is to say, the form of re-grinding mill in which rods are used instead of balls or pebbles. He gives particulars of the Marathon, Marcy, Allis-Chalmers, Cole-Bergman, and Forrester-Hendy types, and also accounts of experimental work done with them. We quote herewith some of his views founded on his investigations and experience.

Rod or roller mills are being actively developed by several companies and have every possibility of being successful competitors of ball and tube mills in certain fields of work. They are adapted only to grinding through a comparatively narrow size range in individual mills, and work done up to this time indicates that they cannot take feed as large as is often given to a ball-mill, nor is it yet proved that they are superior or equal to tube-mills where material finer than 100 mesh is desired. Theoretically, however, there is no reason why they should not be efficient grinders for the finest sizes. They do not seem as adaptable to small as to large units, for a small mill could not carry sufficient weight of rods to break up large or tough ore particles, for the rods act along a line contact. They have been successfully used for dry crushing, although this is not generally desired. There seems to be no reason why rods could not be substituted for balls in mills of the Krupp type which discharge through perforated plates forming the cylindrical surface of the mills. The author has never heard of

[illegible] the way, however, removal of the worn rods would be an inconvenience.

In rod-mills, a waved type of liner is probably [illegible]. The indications are that liner consumption will be possibly ½ lb. per ton less than for ball-mills. Also, the forms are simpler and can be made more cheaply. There are no grates or manholes to provide for. The consumption of steel rods appears to be slightly less in the rod-mill than of balls in the ball-mill. In this connexion it is important to remember that steel in the form of rods or rounds is a standard article, cheaply made, and obtainable from many rolling-mill plants. Competition is active, and there are no trade-name handicaps. Statistics covering several years indicate that balls sell for about double as much as rods. Freight, however, will be perhaps half of the delivered cost and is about the same for rods as for balls. Power consumption would seem to be somewhat less as a general rule for rod-mills than for ball-mills of equal capacity, the exact figures depending upon the grinding problem and the type of mill selected.

Indications are that flotation concentrates are more easily filtered when the ore has been ground in rod-mills than when balls have been used as the grinding medium. If this be true, it would seem to be a logical result of the lessened amount of slime produced in rod-mill grinding, inasmuch as it is this which clogs the canvas and results in a thin and wet filter cake.

Most of the rod-mills described by the author have not been in use long enough to prove the extent of their applicability or to afford fair comparisons with ball-mills or tube-mills. The information given indicates possibly more of their advantages than disadvantages.

Origin of Graphite.—In *Economic Geology* for May, Thomas H. Clark, of Harvard University, discusses the origin of graphite at the contact of igneous and metamorphic rocks. He quotes a paper by K. L. Alling appearing in the New York State Museum *Bulletin* for 1918. Alling showed that the oxides of carbon in the presence of gaseous water may react to form graphite. Much of this water may be magmatic, or the heat of the intrusive igneous rocks may release water from sedimentary rocks ; while one of the sources of carbon dioxide may be calcium carbonate. The author also quotes H. P. H. Brumell's paper in the *Journal* of the Canadian Mining Institute, 1908, who suggested that intrusives, in conjunction with siliceous or other waters, acted upon the original rocks, and formed sulphates and silicates, at the same time depositing the carbon as graphite. The author proceeds to discuss opinions on the subject of A. N. Winchell, H. Dixon, and E. G. Acheson. He concludes thus : "Granting that the chemical processes upon which Dixon, Winchell, and others base their formulas are correct, the geological materials required are water and carbon monoxide or carbon dioxide. There is evidence that these latter substances might come from the calcite of the limestones. Among the contact metamorphic minerals developed between igneous rocks and limestone the most abundant are lime-bearing minerals, two of which, scapolite and diopside, are almost exclusively confined to meta-limestones. Therefore, it seems probable that, if the limestone furnished the lime (CaO) for the silicates, the remaining carbon dioxide (CO_2) furnished the material for the graphite. Of the two derivatives of the calcite, the carbon dioxide would be the more volatile, and therefore the less likely to be caught and crystallized. On account of this, it may be, the graphite is frequently not found actually at the contact, but separated from the igneous rock by lime silicates, which were less volatile. Just what the conditions are that result in the crystallization of the graphite remain to be established."

SHORT NOTICES

Winding Engines.—In the *Colliery Guardian* for June 17, C. D. Mottram commences an article on the graphical dynamics of a winding engine.

Shaft-sinking.—In the *Engineering and Mining Journal* for May 21, E. R. Rice describes the sinking of Van Dyke No. 1 shaft, Miami, Arizona. This was the locale of the champion shaft-sinking exploit referred to in the *Journal* a year ago.

Compressed-air Shovel.—The *Colliery Guardian* for May 27 quotes a paper by M. Clapier read before the Société de l'Industrie Minerale describing an underground shovel operated by compressed air intended for filling coal into cars and filling worked-out stopes.

Air in Mines.—The Institution of Mining Engineers has published the third report of the committee on the control of atmospheric conditions in deep and hot mines, with which is embodied a paper on the subject, written by J. P. Rees.

Bore-hole Survey.—The *Engineering and Mining Journal for* June 4 describes the Wuench "graviscope", an instrument for continuously recording the direction of bore-holes.

Drill Steel.—In *Chemical and Metallurgical Engineering* for June 1, P. A. E. Armstrong describes experimental work in producing hollow drill steel with a decarburized interior surface.

Drill Steel.—The American Institute of Mining and Metallurgical Engineers has published the following papers on drill steel : Analysis of Some Drill-Steel Tests, by F. B. Foley ; Application of Magnetic Analysis to Rock-Drills, by C. W. Burrows ; Heat Treatment of Rock-Drill Steel, by G. H. Gilman ; What is the Ideal Drill-Steel ? by F. H. Kingdon ; Rock-Drill Steels too Short for Use Reclaimed by Welding, by W. T. Ober.

Zinc Dust and Vapour.—*Chemical and Metallurgical Engineering* for May 25 contains a translation of an article in a Norwegian paper on the nature of zinc dust ; and for May 18 of an article on the condensation of zinc vapour.

Zirconia.—The *Journal* of the Society of Chemical Industry for June 15 contains a brief paper by Dr. W. R. Schoeller on the production and testing of zirconia.

Estimation of Arsenic. — The *Chemical Trades Journal* for June 25 reprints a paper read by R. Leitch Morris before the British Pharmaceutical Conference on the volumetric determination of arsenic acid.

Philippine Mining.—In the *Engineering and Mining Journal* for June 4, C. M. Eye writes on mining progress in the Philippine Islands.

Chuquicamata Copper.—In the *Mining and Scientific Press* for June 4, A. W. Allen commences an article on the Chuquicamata copper enterprise in Chile.

Drying Problems.—The *Journal of Industrial and Engineering Chemistry* for May contains a number of papers dealing with various problems connected with the commercial drying of materials.

Alaska Juneau.—In the *Mining and Scientific Press* for May 7, V. C. Clauson gives the history of the Alaska Juneau gold-mining enterprise, and an account of the concentration and metallurgical plant.

Spitsbergen.—The *Iron and Coal Trades Review* for May 27 quotes a description from the Dutch Official Economic Intelligence, of the coal concessions acquired by a Dutch company from the Isefjord Kulkompani of Christiania. The property is on Ice Fiord, to the east of Green Harbour.

Coal in Yugoslavia.—The *Iron and Coal Trades Review* for June 17 contains an article by D. A. Wray on the coal resources of Jugoslavia, the new kingdom of the Serbs, Croats, and Slovenes.

Geology of China.—The *Geological Magazine* for June commences the publication of a paper entitled "An Outline of Chinese Geology", by J. S. Lee, lecturer on Paleontology in the University of Peking.

Felspars.—The *Journal of Geology* for May is devoted entirely to Part I of "The Mineralography of the Felspars", by H. L. Alling.

D. W. Brunton.—The *Mining and Scientific Press* for May 28 publishes an interview with D. W. Brunton by T. A. Rickard.

RECENT PATENTS PUBLISHED

☞ *A copy of the specification of any of the patents mentioned in this column can be obtained by sending 1s. to the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. 2, with a note of the number and year of the patent.*

19,015 of 1919 (163,348). W. J. Nüranen, Helsingfors, and A. Hibbert, Bexhill. Method of separating metals, such as copper and iron in sulphide ores, by roasting to oxide and exposing the mixture to the preferential treatment of a gaseous acid radicle.

19,028 of 1919 (162,682). W. J. Browning, Rio Tinto. An industrial process for the extraction of metals from solutions or for the separation of metals, consisting in precipitating in the form of a sulphide or sulphides one or more metals present in solution by reaction with elemental sulphur and sulphuretted hydrogen produced by burning or calcining or distilling a sulphur-bearing mineral or minerals, such as pyrites or cupriferous pyrites, in the presence of steam additional to that which may arise from the moisture in the material or atmospheric air used, and then passing the residual gas through an incandescent carbonaceous zone while regulating the supply of oxygen and maintaining the optimum temperature of the carbonaceous matter.

19,581 of 1919 (162,307). W. H. Dorman & Co., M. L. Bramson, J. Hanson, and R. G. Hanson, Stafford. Improvements in the construction of wave-transmission rock-drills.

773 and 26,939 of 1920 (163,080) and 6,429 of 1921 (163,659). J. M. Holman and A. T. Holman, Camborne. In air-feed rock-drills, automatic means whereby the drill is rotated without impeding the forward feed.

2,580 of 1920 (138,348). Rare Metals Reduction Co., Baltimore. Method of producing ferro-zirconium.

3,181 of 1920 (131,622). T. A. Eklund, Stockholm. Method of recovering tin from tin ashes and waste tinplate.

3,256, 7,470, and 22,687 of 1920 (162,775). C. J. Williams, London. Improved methods of adjustment for table concentrators.

4,067 of 1920 (163,423). A. J. Dubois, Sarrebruck. Means for loading and unloading mine cages having several decks.

4,983 of 1920 (163,474). O. Reynard, Bradford, and E. Edser, London. Rust-prevention composition for protecting metallic surfaces. The following are claims 1 and 3: (1) A method of preparing a composition for the protection of surfaces, in which anhydrous wool-fat, substantially free from free fatty acid is mixed with a solvent free from water, which will have no injurious effect on the surface and which consists of a non-imflammable volatile liquid, such as trichlorethylene or carbon tetrachloride (or contains sufficient thereof to render the solvent non-imflammable). (3) A process according to Claim 1 of preparing a protective composition in which any crude substance which contains wool-fat and also contains fatty acids, is treated with an oxide, hydroxide, or a suitable salt of a metal which will combine with the free fatty acid to form a metallic soap, preferably a soap insoluble in water, and the product, after evaporating off any water present, is treated with a non-imflammable volatile solvent such as trichlorethylene or carbon tetrachloride or a solvent containing sufficient thereof to render the liquid non-imflammable.

5,228 of 1920 (139,220). J. E. Kennedy, New York. Improvements in jaw-type rock-breakers.

7,027 of 1920 (163,170). Traylor Engineering and Manufacturing Co., Allentown, Pennsylvania. Improvements in gyratory crushers.

7,645 of 1920 (162,486). T. G. Nyborg, Hexham, and M. F. Higgins, Sheffield. Improvements in hand hammer-drills.

8,468 of 1920 (140,775). G. Grondal, Djursholm, Sweden. Slime separating machine.

11,934 of 1920 (155,792). Electrolytic Zinc Co., of Australia, Ltd., Melbourne. In the recovery of zinc by electrolysis, in which lead anodes and aluminium cathodes are used, the removal of chlorine from a zinc-bearing solution prior to electrolysis by adding a soluble silver salt, thereby preventing the corrosion of the electrodes.

13,579 of 1920 (163,210). R. H. McKee, New York. Method of producing zinc oxide and hydrogen by bringing zinc vapour into contact with steam.

17,392 of 1920 (145,710). Fried. Krupp, Essen, Germany. Improvement in the inventor's method of producing low-carbon ferro-chrome.

18,346 of 1920 (146,372). Anschutz & Co., Kiel. Gyroscopic compasses suitable for surveying purposes.

18,964 of 1920 (147,020). Manufactures de Produits Chimiques du Nord, Paris. Deposition of dust from the gases of ore-roasting furnaces by means of hanging chains.

18,967 of 1920 (161,103). Ore Roasting Development Co., Philadelphia. Multiple hearth ore roasting furnace.

19,668 of 1920 (147,686). V. Antoine, Belgium. Improvement in disc crushers and grinders.

20,131 of 1920 (148,210). R. von Zelewski, Hennef, Germany. Improvements in vertical retorts used in the distillation of zinc.

24,280 of 1920 (150,997). H. W. Hardinge, New York. In conical mills fitting a conical hood to the discharge end and revolving with it, the duty of the hood being to arrest the particles that are too big and to return them to the body of the mill.

NEW BOOKS, PAMPHLETS, Etc.

[illegible] can be obtained [illegible] *The Mining Magazine*, [illegible] Wall, E.C. 2.

Salt: Asbestos; Mica: Molybdenite; Platinum: Nickel: Graphite: Manganese. By B. DUNSTAN, Chief Government Geologist for Queensland. These little pamphlets are reprints, revised, of articles that have appeared in the *Queensland Government Mining Journal* during the last year or two. Attention has been drawn to these articles on several occasions in our pages, and some have been quoted in connexion with the information given relating to the Australian deposits.

Text-book of Inorganic Chemistry, Vol. IX, Part 2. Iron and its Compounds. By DR. J. NEWTON FRIEND. Cloth, octavo, 270 pages, illustrated. Price 18s. London: Charles Griffin & Co., Ltd.

Metallography. Part II. The Metals and Common Alloys. By SAMUEL L. HOYT. Cloth, octavo, 470 pages, illustrated. Price 28s. net. New York and London: McGraw-Hill Publishing Co., Ltd.

COMPANY REPORTS

Robinson Deep.—This company belongs to the Consolidated Gold Fields group, and works a deep-level property in the Central Rand. The Booysens property on the dip was acquired more recently, and a new vertical shaft, the "Chris", was sunk. The operations have not been profitable, and the company is saddled with special "A" shares, entitling the holders to large cumulative preferential dividends, which are in arrears, and there is also a loan of £300,000 advanced by the Gold Fields and Central Mining. The report for 1920 shows that 625,150 tons of ore was raised and sent to the mill, where 196,474 oz. of gold was extracted, being 6·29 dwt. per ton. The receipts from the sale of gold were £1,100,693, of which £277,139 represented premium. The working cost was £912,040, and the working profit £188,652. Interest, taxes, etc., absorbed £60,634, and £76,471 was allocated to capital account for shaft-sinking. The holders of "A" shares received £50,000. The revenue per ton was 35s. 3d., and the working cost 29s. 2d. It will be seen that but for the premium a considerable loss would have been made. The ore reserve is estimated at 1,597,000 tons, averaging 6·97 dwt. per ton, the total being much the same as the year before, while the content is 0·38 dwt. higher. In order to develop the deepest ground, it is proposed to sink an auxiliary vertical shaft, at the cost of a quarter of a million pounds.

Planet-Arcturus Gold Mines. — This company belongs to the Gold Fields Rhodesian Development group, and owns the Planet, Arcturus, Slate, and other properties. Early operations were not successful. In 1918 the Slate and Arcturus were leased to the parent company, which advanced working capital on loan. Milling was recommenced in June, 1920. The report for 1920 shows that from that date to the end of the year 30,603 tons of ore was treated for a yield of 12,968 oz., which sold for £73,400, including premium. The working cost was £48,843, leaving a working profit of £24,557, which was applied in reducing the debt to the lessees. The balance of expenditure incurred by the lessees, with accrued interest, amounted on December 31 to £159,657. The main shaft was sunk to water-level at 335 ft. The small amount of development work done has given generally satisfactory results.

Tronoh Mines.—This company has been working alluvial tin properties in Perak, Federated Malay States, since 1901, and has been a large and important producer. The best parts of the properties have been worked out, and recent policy has been to build dredges for the treatment of the poorer ground and tailings, and to let ground on tribute. The report for the year 1920 shows that there has been a further fall in the value of the ground treated. Two dredges were at work and another is in course of erection on the spot. No. 3 mine was worked by pump-dredge. By far the largest proportion of the output was done by tribute. The exact returns were: 51 tons of tin concentrate from No. 3 mine, 43 tons from 239,491 cu. yd. No. 1 dredge, 272 tons from 819,091 cu. yd. No. 2 dredge, and 759 tons from tributers, total 1,125 tons. The accounts show an income of £218,372, and a net profit of £21,463, out of which £20,000 has been distributed as dividend, being at the rate of 10%.

Lahat Mines. — This company belongs to the Tronoh group, and has operated alluvial tin properties in Perak, Federated Malay States, since 1906. The report for 1920 shows that the output of tin concentrate has been increased by the adoption of a drifting system at one of the properties, by means of which a rich lead is followed cheaply. The total output was 533 tons, as compared with 465 tons in 1919. At the underground workings 27,670 cu. yd. was raised and 333 tons of tin concentrate extracted from it, the yield being 28 lb. per cu. yd. The accounts show an income of £101,144, and a net profit of £15,173, out of which £12,000 has been paid as dividends, being at the rate of 10%.

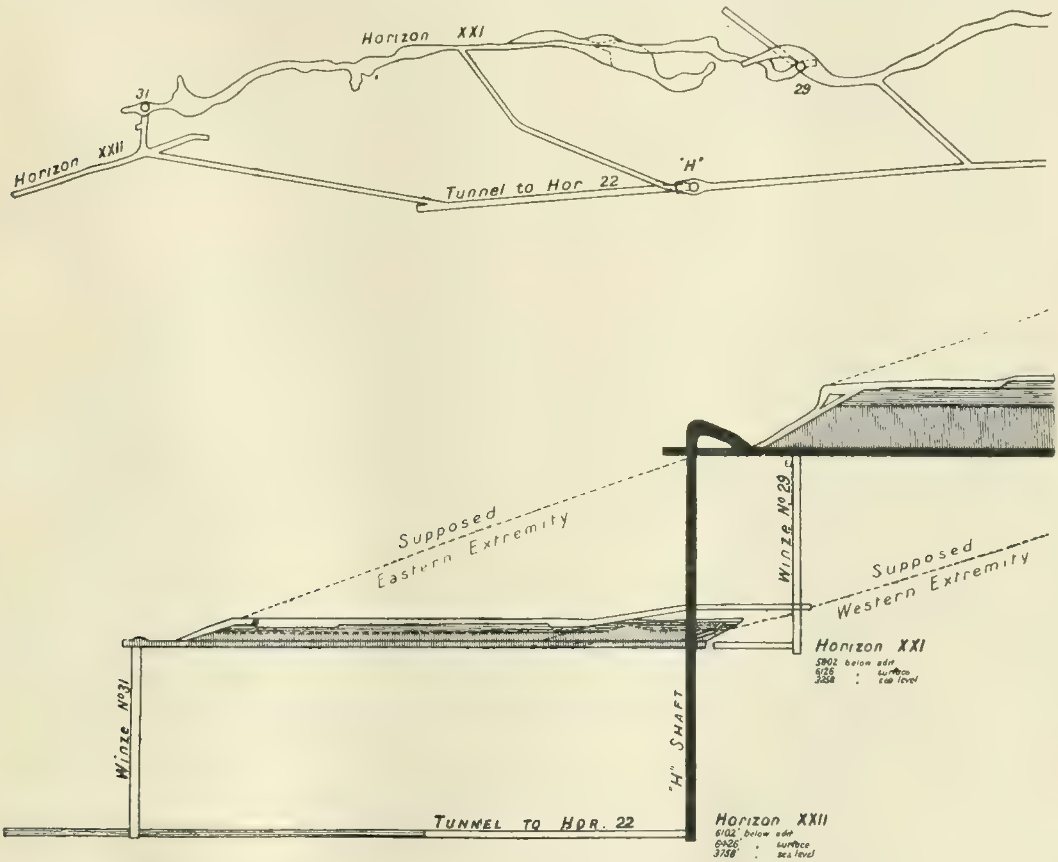
Sungei Besi Mines.—This company belongs to the Tronoh group, and was formed in 1909 to work alluvial tin properties in the State of Selangor, Federated Malay States. The report for 1920 shows that 197,706 cu. yd. yielded 363 tons of tin concentrate, selling for £65,653. Additional land is being acquired to the north, where boring is now in hand. The company has during the past year worked the Kepong property, where 121 tons of tin concentrate was extracted from 230,000 cu. yd. of ground sluiced; at the present price of tin, however, the operations are not profitable. The accounts show receipts £83,815, and a net profit of £17,615, out of which £16,711 has been distributed as dividends, being at the rate of 15%.

Ex-Lands Nigeria.—This company was formed in 1912 to work alluvial tin properties in the southern part of the Bauchi Plateau, Nigeria. The report for the year 1920 shows that 382 tons of tin concentrate was produced, as compared with 360 tons in 1919, and 340 tons in 1918. A pumping plant was recently supplied in order that the rate of extraction might be increased, but owing to general conditions and to the high cost of wood fuel, its use is postponed for a time. At the end of 1919 it was estimated that the company's ground would yield 2,000 tons of tin concentrate. The accounts show a profit of £14,130, of which £8,343 was placed to reserve for income tax, while £6,745 was distributed as dividend, being at the rate of 5%.

Le Roi No. 2.—This company was formed in 1900 by the late Whitaker Wright to work a group of gold-copper mines at Rossland, British Columbia. For the last eighteen years operations have been

conducted under the direction of Alexander Hill and Stewart. The report for 1920 shows that 16,422 tons of ore was shipped to the smelters, averaging 0·878% copper, 12·4 dwt. gold, and 0·71 oz. silver, the gross value of which was $271,742, or $16·55 per ton. The total smelting charges were $122,126, or $7·43 per ton. The loss for the year was £12,181. The work was conducted under exceptional difficulties, owing to the high costs of material, labour, and to the inability of the smelters to handle and pay for the ore promptly. It has been necessary, therefore, to suspend mining for the present. No ore has been sent to the concentration plant recently, but as there has been a considerable increase in fine ore that cannot be hand-sorted, it has been decided to introduce a Minerals Separation plant.

St. John del Rey. — The nintieth annual report of this company, which works the Morro Velho gold mine in Brazil, shows that the output was restricted chiefly owing to scarcity of labour, caused by the unpleasantly hot conditions in the deepest levels. Toward the end of the year the cooling plant came into operation, and the cause of dissatisfaction being removed, more men have been available since. The ore raised and treated was 146,800 long tons, as compared with a normal 180,000 tons. The yield of gold was 98,311 oz., worth £418,210 at par, and the sale of silver brought an income of £4,888. The premium received on the sale of gold was £126,811, so that the total revenue was £549,914, or 57s. 8d. per ton. The working cost in Brazil was £352,097, or 47s. 11d. per ton. The net profit was £167,749, of which three-quarters represented the premium on gold. The sum of £85,000 was transferred to capital works account. The usual 10% was paid on the £100,000 preference shares, and 10% was paid on the £546,265 ordinary shares. The chief development work during the year has been the driving of the tunnel at horizon 22, and the sinking of winze 31 from horizon 21 to horizon 22. This was extremely difficult work, owing to the rock temperature being 117° F. When once the connexion was made conditions improved, and as already stated the cooling apparatus further relieved the situation. Under these circumstances it was not possible to maintain the reserve fully nor to keep the normal number of working faces going. The reserve is estimated at 1,228,000 tons, or about 6½ years' supply; though as part of the lode between horizons 21 and 22 has not been fully explored, Mr. Chalmers considers it prudent to reckon the actually proved ore at 827,000 tons, equal to 4½ years' supply. Further reference to this report is made in the Editorial columns.



Plan and Section of Lowest Workings at St. John del Rey.

Buena Tierra.—This company belongs to the Esperanza group, and operates a silver-lead property in Chihuahua, Mexico. Last year additional capital was raised in order to extend the scale of development. The report for 1920 shows that 6,927 tons of oxidized ore was shipped, averaging [illegible] lead and 8·6 oz. silver per ton, for which the smelters paid $63,048, or $9·10 per ton. The accounts show a loss of [illegible]31,619 for the year. Owing to the low prices of lead and silver, the high cost of development work, and the excessive railway rates and smelter charges, it was decided to suspend operations on June 30 of this year.

Esperanza.—This company has worked the Esperanza gold mine at El Oro, Mexico, since 1903. Large profits were made for some years, but operations are now confined chiefly to the treatment of low-grade ore, old fillings, and tailings. The report for 1920 shows that 273,120 tons of ore was sent to the mill, where gold and silver realizing $1,370,555 was extracted. The loss at the mine was $406,491, after allowing for depreciation of plant and depletion of the mine. The reserve of ore and filling is estimated at 117,684 tons, together with 750,000 tons of lower grade material that might show a profit in normal times. As has been recorded from time to time recently, development is being actively continued and has occasionally disclosed high-grade ore. The company has an option on the Union en Cuale property, where active development has been done. Owing, however, to the unsatisfactory state of the metal market, it has been deemed best to suspend this work, though the option is being continued.

Esperanza Copper and Sulphur.—This company was formed in 1906 to work a group of pyrites mines in the south of Spain. Shipments have been maintained fairly steadily, and operations were not disturbed by the war to the same extent as those at other mines in the district. The only year when there was serious restriction was 1919, during which the shipments were only one-third of the normal. The report for 1920 shows that the output of pyrites was 71,176 tons, and that 85 tons of copper precipitate was produced. The dispatches of pyrites from the mine to the port of Huelva were 61,719 tons, and the shipments thence 82,970 tons. If it had not been for a railway strike, which occupied ten weeks, the normal shipments of 100,000 tons a year would have been reached. The reserve of developed ore is estimated at 835,000 tons. The accounts show a profit of £14,598, and £17,500, less income tax, has been distributed, the rate being 5%. The company also has a controlling interest in the Cyprus Sulphur & Copper Co., which owns low-grade deposits, the treatment of which is still under consideration.

Great Boulder Proprietary.—This company was formed in London in 1894 to acquire gold mining claims at Kalgoorlie, West Australia, and for twenty-five years handsome dividends have been paid. During the last year or two the output and profits have been smaller, owing to shortness and indifference of labour, high costs, and the arrival of the workings at the bottom limits of the orebodies. The report for 1920 shows that 100,756 long tons of ore, averaging 14·26 dwt. per ton, was raised and treated, yielding gold worth £305,212 at par, to which must be added £123,500 received as premium. The total revenue was £428,713; the working cost was £215,712; allowance for depreciation £25,000, and taxes £47,468. The shareholders received £131,250, the dividends amounting to 75%. Richard Hamilton, the manager, estimates the reserve at 245,187 tons, averaging 14·75 dwt. per ton, as compared with 325,314 tons averaging 14·56 dwt. the year before, and 345,719 tons averaging 14·49 dwt. at the end of 1918. [illegible] new properties, the option on the Maher at Comet Vale has been abandoned, but the O.K. at Norseman is giving good results. The continual rise of costs at Great Boulder is shown by the fact that the cost per ton in 1920 was 41s. 9d., as compared with 35s. 8d. in 1919, and 32s. 6d. in 1918.

Zinc Corporation.—This company was formed in 1905 to treat zinc tailing at Broken Hill by the flotation process. In 1911 the South Blocks mine at Broken Hill was acquired, and the company then became a lead producer as well. The present report covers the year 1920. During this time the mine and plant were largely idle owing to the strike, and it was not until November that mining was resumed, while concentration was not started until the next month. Until the end of the year the lead concentrator treated 6,908 tons of ore, averaging 17% lead, 10·4% zinc, and 2·8 oz. silver per ton, and produced 1,620 tons of lead concentrate, averaging 63·8% lead, 7·1% zinc, and 9·2 oz. silver; together with 2,212 tons of zinc tailing, averaging 18·5% zinc, 4·2% lead, and 1·6 oz. silver. At the zinc concentrator 28,110 tons of tailing and slime was treated, of which 24,920 tons came from the old dump, averaging 16·4% zinc, 4·1% lead, and 5·1 oz. silver, and produced 7,670 tons of zinc concentrate, averaging 48·2% zinc, 6·9% lead, and 8·7 oz. silver, together with 542 tons of lead concentrate, averaging 54·3% lead, 17·9% zinc, and 24·5 oz. silver. Since the end of the year it has been found impossible, with the high wages and the low price of lead, to continue the production of lead concentrates; moreover, there was a fire at Port Pirie smelting works, as already recorded. The only operation conducted at present is that at the zinc concentrator, and the zinc concentrate produced is sold to the Government under the contract made shortly after the outbreak of war. The ore reserve in the mine is estimated at 2,115,700 tons, averaging 14·6% lead, 9·4% zinc, and 2·6 oz. silver. There is also 664,633 tons of dump material to treat, and 31,472 tons of zinc slime. The accounts show an income of £109,132 from the sale of concentrates, and a profit of £31,910, out of which £24,569 was distributed as preferential dividend for the first half of 1920.

Amalgamated Zinc (De Bavay's).—This company treats zinc tailing at Broken Hill, and until recently was mainly occupied with the treatment of this material coming from the North and South mines. At present old dump material occupies chief place. The company has a large holding in Electrolytic Zinc of Australasia, and also conducts experimental work in other directions. The report for the half-year to December 31 last shows that work was resumed in the middle of November on the termination of the strike, and during the six weeks to the end of the year 14,852 tons of material was treated for a yield of 3,403 tons of zinc concentrate, averaging 47·7% zinc, 6·7% lead, and 13·4 oz. silver per ton, together with 32 tons of lead slime concentrate, averaging 48·6% lead, 15·7% zinc, and 76·6 oz. silver. The accounts show a loss of £16,651 on the half year.

EDITORIAL

ON July 25 the Institution of Mining and Metallurgy moved to its new premises in City Road. The house is commodious and well arranged, and though its surroundings are not just what the council would have chosen if office accommodation in London had not been so restricted, it can at least be said that the continuous omnibus and tram services to the City nullify the feared isolation of the new home. The Institution of Mining Engineers has also moved to City Road, and Mr. C. McDermid has assumed the secretaryship of both societies. We give herewith a photographic view of the building, and in a later issue we hope to publish a detailed description.

THE INSTITUTION OF MINING AND METALLURGY'S NEW HOME.

ELSEWHERE in this issue Mr. T. Skewes Saunders describes the mines of the Dos Estrellas Company at El Oro, Mexico. This mine has given big profits to Mexican and French owners from extremely rich ores, and of late years profits have been made by the scientific treatment of the remaining ores of lower grade. Details of the mine have never been published, so that the complete history of the El Oro district has never been available. The present article may serve to fill in some of the gaps. In another part of this issue we reprint a paper by Mr. Horace V. Winchell on the geology of Pachuca and El Oro. His advice as regards El Oro is timely, and should be appreciated by those who are in favour of further exploration.

A BILL before United States Congress relates to the establishment of a Department of Mines, assimilating old offices and creating new ones. It is proposed that the present Bureau of Mines should be converted into a "Bureau" of Mineral Technology, and the Geological Survey into a "Bureau" of Mining and Applied Geology. There would also be a "Bureau" of Mineral Markets, and a "Bureau" of Public Mineral Domain. In addition there would be a "Division" of Mineral Statistics, a "Division" of Publications, and a "Division" of Accounting and Disbursing. By those in this country who are beginning to hate the words "Bureau," "Departments," and "Divisions," this announcement is not received with enthusiasm.

NOT long ago a note was published in these columns relating to the gyrostatic compass, and to the possibility of its application to mine surveying as a substitute for the magnetic compass in indicating the true north. Surveyors in

this country were aware at the time that an instrument embodying this idea had been developed in Germany, but no one could give details. Attention may therefore be drawn to the abstract of the patent issued to Anschutz & Co., appearing elsewhere in this issue. The specification and drawing give an idea of the principle of the instrument, but we hope in a future issue to publish further information supplied by the makers.

THE Cornish Chamber of Mines Year-book for 1921, edited by Mr. Harold E. Fern, is a reflex of the contracted state of local mining, but in the comparatively few pages a great deal of valuable history and statistical information is given. These records are valuable both currently and for permanent reference. The contents of the volume include the report of the Council for the year 1920, details of the various metal-mining companies operating in Cornwall, and statistical tables of production. A valuable feature of the volume is a table giving analyses of the working costs during 1920 at five of the leading tin mines; namely, East Pool, Dolcoath, South Crofty, Tincroft, and Geevor. These figures explain why costs have been advancing so seriously during the last few years.

WHETHER gold is to go back to its original value, or whether we are to continue to send the metal to the United States and live on paper in this country, is the chief financial problem of the day. The only orthodox way of bringing gold back to its par value is to cut wages and public expenditure in this country. In this issue we publish an article by Mr. S. J. Speak, who demonstrates the inability of the Government and the financial authorities in the City to effect this desirable reinstatement of the basic principle. Mr. Speak's opinion is that the appreciation of gold should be regularized, and that its price should be put to six guineas per ounce. In this way the relation of prices to values would be more easily revised without the working-classes being provided with a reason for strikes. The relation of gold to official currency is one of those difficult problems that a layman, even a professor of political economy, cannot always grasp, but there are cases, allied to mathematical "limits," which are easily comprehensible. For instance, the great discoveries of gold in Australia and California had both a sudden and an ultimate influence on currency and wages, and gold as such suffered a depreciation; while, on the other hand, the uncontrolled issue of paper money by the Confederates and by various Governments in South America caused nominal prices to go up indefinitely. In the depreciation of money by the State gold is not in the hands of the public, so they reap no benefit against the fall in its purchasing value, the matter being entirely in the control of the exchange bankers. The fact is that the public have no control of the price of gold, or even of diamonds, and the disposal of either is in the hands of the rings. Mr. Speak's article gives, under the circumstances, an intelligible solution of a much-debated question.

LAST month we recorded that Mr. Bradley Stoughton had resigned the secretaryship of the American Institute of Mining and Metallurgical Engineers. Since then it has been announced that he is succeeded by Mr. F. F. Sharpless. Mr. Sharpless will be known to many people in London, for he was at one time an adviser to the Consolidated Mines Selection Company, and in this capacity he visited West Africa. He has been professionally associated with Mr. Horace Vaughan Winchell, and with other influential men who devote much time and thought to the interests of the Institute, and he has been secretary of the Mining and Metallurgical Society of America. So he is well known to mining engineers and experienced in society administration. But while thus prognostigating success for his tenure of office, we still cannot help expressing our inability to understand why Mr. Stoughton should have felt it incumbent on him to resign. The secretaryship of the Institute has not provided the only worry to the council recently, for the publication of the monthly paper *Mining and Metallurgy* is also the cause of grave concern, and the multiplicity of unwieldy committees is once more being adversely criticized in various quarters. As regards the monthly paper, we notice that the *Engineering and Mining Journal* expresses its disapproval of it, both from the point of view of policy and in relation to its intrinsic merits. With sly subtle humour the writer shows how little original matter is found in its pages, and how it fails to serve the requirements of the mining engineer and metallurgist. The humour is so subtle that we are unable to say whether the fact of *Mining and Metallurgy* having

somewhat of the flavour of THE MINING MAGAZINE but not so compact" is intended as a compliment to both, either, or neither of the monthlies mentioned ; probably neither. But seriously, the *Journal* is to be congratulated on the stand it has taken, for its advice and comment will go a long way. It is to be hoped that the Institute will revert to its *Bulletin*, and at the same time go back to its old policy of quality rather than quantity in the matter of papers published. We note in the American papers some reference to a proposal to amalgamate *Mining and Metallurgy* with the organ of the American Mining Congress. Surely such a step would put the Institute still further off the mark, and would be regarded with dismay by mining engineers outside the United States.

Rhodesia Broken Hill

In these days of depression in the metal markets it is remarkable that a lead mine in the centre of Africa should be making profits and paying dividends. But this is what, in spite of so many disadvantageous circumstances, the Rhodesia Broken Hill Development Company has been able to do. During 1920 the yield of lead was 14,602 tons, obtained by smelting 42,806 tons of ore ; the net profit, after allowance for depreciation, was £89,949, out of which £35,000 was paid as dividend, at the rate of 10%, the remainder being kept in hand until income tax and excess profits duty are settled. The deposit belonging to this company, situated in Northern Rhodesia, is one of the most interesting of all those controlled in London, and we were glad to be able to publish a detailed account of it in October, 1919. In glancing briefly at the report of current progress, it is not necessary to review past history or to give a general description of the property, for the article in question contains all this information. During the last year or two further geological investigations have been made, and it is now considered certain that the various outcrops are parts of two lodes about 1,000 yards apart. One of these lodes outcrops at kopjes Nos. 1, 3, and 4, and contains more lead than zinc ; while the other passes through kopje No. 2 and consists essentially of zinc ore. There are a number of other outcrops, of minor importance at present, which have not yet been explored in depth. The further development of the ore, and also the theory of the geology and the origin and continuance of the ore deposits, depend largely on the water question. As recorded two years ago the surface-workings are drowned with water, and it was an open question whether pumping would be effective at anything like a commercial cost, and consequently whether it would be possible to sink shafts. The directors decided to provide powerful pumps, which were eventually delivered after great delay, and at enhanced prices. They also called to their service the Francois cementation process, by means of which shaft-sinking became possible immediately, and should continue to be independent of the water. The No. 1 shaft has been sunk to 173 ft., and a level is being opened at 150 ft. By means of these workings, it will be possible to follow the indications provided by the bore-holes. In connexion with the water, which has given so much trouble, and has also worried the geologists, it has been shown recently that the water-level is now much higher than it used to be, and that a drainage channel 300 ft. deeper than the present water-level was in action at no distant date. Thus the existence of oxidized ores below the present water-level is explained, coupled with a certainty of the permanence of sulphide ores below the portions already proved by bore-hole. A hope is also provided for an eventual clearance of the water from an apparently waterlogged area. Another interesting geological point relates to the occurrence of vanadium minerals. During 1920 a substantial income was derived from the sale of these ores, and arrangements are being made for their further exploitation. At the present time the proved vanadium reserves consist of 3,750 tons, averaging 7 to 13%, and 6,000 tons averaging $3\frac{1}{2}$%. Experimental work is in hand for the concentration of these lower-grade ores, and eventually it is believed that vanadium will be an important factor in the success of the property. As regards the zinc contents of the ores, it is only necessary here to say that electrolytic plant is on the spot, and that results will be available later. In concluding this brief notice, it is right that personal credit should be given. Mr. Edmund Davis, as chairman and managing director, provides the business ability, Messrs. Hooper, Speak & Co. are the consulting engineers, Mr. Ross Macartney is the manager at the mine, and Mr. F. P. Mennell has been engaged in geological studies.

Cornish Conditions

During the last few months we have published no Camborne letter in our news columns, for our local correspondent bluntly says there is nothing to write about: Cornish mining is dead, hopes of resuscitation are remote, and to write of the terrible position and the distress would be unkind to the sufferers. It is to his credit that he fought for the cause of Cornwall during the threatening days, canvassed the practical sympathy of those in power, and foretold the results of the Government's policy of neglect and drift. It is no wonder that he is disgusted with journalism which has proved so ineffective, and has laid aside his pen for the time. But something must be said about Cornish matters, even if it is only with the object of arousing some sympathy for the victims of adverse circumstances. Of the men who are perforce idle, it has to be said that they were never overpaid and that they never upset normal arrangements by making impossible demands. In fact there have been cases where they have suggested a curtailment of pay in order that operations should not cease. Their attitude has been entirely different from that of the coal-miners, who induced the Government to pledge public funds for the maintenance of high wages in a prosperous industry that can pass the extra cost to the consumer. The tin-miner was faced with the higher cost of coal, steel, timber, and explosives, and he was quite unable to pass the extra costs to the buyer of his products, for the metal markets are entirely beyond his control; while, as for assistance from the public purse, this was not granted until wages were not forthcoming. It was always the contention of the MAGAZINE that the mines should be kept working by aid of the public money now distributed as charity and without profit to the giver or the community, though it was fairly clear that the proposition would stand no chance of acceptance. It is too late now to revive an argument in favour of such a course. All that can be done is to help the miner in some practical way and to break the appalling darkness and silence that broods over Cornwall. The out-of-work pay is little enough, and is quite insufficient for keeping life together with decency and respect; but now even this resource is threatened, and the men never know when they will be entirely without means of subsistence. The funds at the disposal of the poor law guardians are already strained to the limit. Voluntary contributions have been liberal, and the Central Relief Committee at Camborne has been able to be of great assistance, but as the days drag by it becomes increasingly difficult to obtain the necessary funds locally. Early this year Mr. Joseph H. Cock, a member of the staff of the Mining School, who was at the time chairman of the Relief Committee, issued an eloquent appeal to Cornishmen abroad to contribute to the funds for the help of distressed folks at the old home. It is gratifying to know that the response was excellent, and that much good was thereby done. Time has since passed and the position in Cornwall is still tense, so we re-echo Mr. Cock's invitation, and trust every Cornishman who reads this article will lose no time in getting into contact with the secretary of the Camborne Relief Committee, the Reverend W. A. Bryant. Before concluding we would mention that many people not conversant with mining conditions recommend the present distressed Cornishmen to emigrate as their fathers and grandfathers did at former periods of mining depression in the old county. Unfortunately it is difficult to follow this advice, for the countries where additional mining labour is wanted are few and far between. Nevertheless if any influential Cornishman abroad can guarantee positions for stranded miners at present in Cornwall his assistance in this direction will be as welcome as a subscription to the funds.

This is the position of things in Cornwall at present. Oh, the pity of it that the sons of an ancient and honourable industry should have to plead for help through no fault of their own!

The Framing of Mining Laws

Reference has been made in these pages on one or two occasions to the excellent work done by the Indian Government in the control of industrial operations. At a time when Indian affairs looked gloomy, and even ugly, a number of sound and experienced servants of the State rallied to its support, and by the exercise of firmness and patience have guided the community to commercial and political safety. Unfortunately the English Press tells us little or nothing of what goes on in the Overseas Dominions, so that the transcendent abilities of Sir Thomas Holland as an administrator are comparatively unknown in this country. The Indian Government has, however, recognized the uses of

publicity, and has made a number of innovations tending to bring its motives and aspirations to the notice of the political and business communities, both locally and in this country. For instance, an Indian Trade Commission has been established at Winchester House, in the City, and many of our readers will have had the advantage of the help and advice of Dr. J. Coggin Brown, who has been found at that office for the last year or so, in connexion with the mineral industries of India and neighbouring countries. More recently the Government has founded the *Journal of Indian Industries and Labour*, with the object of providing a means of contact between the various industrial communities throughout India, and of explaining the underlying principles on which the Government acts. It may be said at once that the Government of India aims at idealism tempered with business acumen. The benefit of the State is the watchword; but, on the one hand, the benefits are not to be entirely controlled by the business man, and, on the other, the State is not to be represented by the blatant agitator or the fluent ignoramus. In fact, it is a combination of the high-mindedness of President Wilson and General Smuts with the mundane philosophy of Cecil Rhodes.

An excellent example of the straightforwardness of the Indian Government is to be found in the May issue of the beforementioned *Journal*, where Sir Thomas Holland writes on the principles governing the grant of mineral concessions in India. Sir Thomas, being alarmed at the apparent simplicity of his exposition of the principles, declares, with his characteristic vein of irony, that "these general considerations are mostly platitudes"; but as all knowledge and mental exercises when clearly expounded may be mistaken by some people for platitudes, we can easily imagine the smile on his face when he wrote or dictated that word. Briefly, the mining laws of India are so framed as to offer sufficient speculative attraction to the capitalist, and at the same time ensure a fair return to the State without undue waste of the natural resources. It is the business of a mining company to make as much profit as possible out of a mineral deposit in the shortest time; this is extravagance from the point of view of the community. On the other hand, the State must see that its mineral resources are utilized for, following their judicious employment, there comes great commercial advantage and prosperity. Yet, seeing that these resources are limited, care must be taken that they are not carelessly or wastefully mined; in other words, complete and gradual extraction is better for the community than rapid profit-making by the mining companies. Sir Thomas puts the case of the miners quite candidly. He points out that, as most mining enterprises are highly speculative, the investor wants the encouragement of generous terms before he will risk capital in an unproved country; that most of the capital is sunk in an irrecoverable form, for the miner cannot sell his shafts and levels in the open market, and he must therefore hope to recover his initial outlay from his profits in a relatively short period; and that unless a miner can now and then reap the benefit of an occasional windfall, he will not be able to write off the losses due to the large number of unlucky ventures inevitable in this class of work. To weigh all these considerations without prejudice or bias is the aspiration of the Indian Government, and, as Sir Thomas says, the expression of these principles looks like a platitude. But how many other countries can point to so clear an exposition of their motives? In other States we see indifference to public or private interests, or an inclination to opportunism, or a participation on the part of the State or its minions in the clash of the markets, in the manœuvres for position, and in the crushing of opponents or rivals, or even a policy which puts business in the way of lawyers and experts.

Sir Thomas Holland, in his article, proceeds to details on one or two debatable points. He gives reasons why the law should be uniform throughout all the Indian States, and he shows why it is necessary to revise the law periodically. He discusses the relation of prospecting licences to mining leases. Here he shows how it is necessary to give liberal terms to the genuine prospector and the obviously earnest investor, and he indicates the necessity for differentiating between the various fields of enterprise. In some cases the surface indications are such as to make it imperative for definite results to be available in a comparatively short time; whereas, in other cases, such as drilling for oil, much longer periods of prospecting should be allowed.

We may be permitted to express the hope that directors will read Sir Thomas Holland's article, for it incidentally gives an excellent

idea of the actual importance of mining relative to other local industries. Most of the companies and their directors are fully aware of their duty to the laws and customs of the various countries, as well as to their own shareholders, but occasionally companies, or groups of companies, come into undesirable and unnecessary conflict with communities and their governors by exaggerating their claims to recognition and by want of capacity to regard affairs in their true perspective. A perusal of this article may act as a corrective.

The Forces of Nature

In this issue we print an article by Mr. J. H. Goodchild, entitled, " Land Growth," which, we readily admit, is not easy to comprehend at the first perusal. The casual reader and even the expert geologist and petrologist may possibly be mystified, as they were with the articles by the author's brother, Mr. W. H. Goodchild, on the origin of igneous ore deposits, which appeared in these pages three years ago. Nevertheless, the author's views will find response in the minds of many students of geology who feel that there is something missing in the theories taught in the textbooks. At the present time the mineral arrangement and the constitution of the earth's surface is ascribed to either igneous action or sedimentation, that is to say, some rocks are held to be the cooling products of a molten magma, while others are the result of meteoric action on existing land surfaces. Mr. Goodchild would add to these influences the chemical reactive energies of the minerals and mineral masses. These chemical forces are, of course, well enough known to geologists, but hitherto argument involving them has been confined to discussions as to the origin of underground ore deposits. Under the latter conditions the potency of solutions to attack, convey, and precipitate are fully recognized, and deductions are facilitated by the fact that material exists concurrently in both the original form and as middle and final products. Few geologists have attempted to apply the same principles to the wider field, and this application is rendered the more difficult because only the current product is visible. This difficulty may be exemplified by reference to the permanence or otherwise of old buildings. The remains of Roman and Egyptian edifices lead people to suppose that the ancients knew better how to build than we do nowadays, they entirely forgetting that the evidence of bad building in the olden days has long since disappeared. Another difficulty in applying this principle in its wide sense is that different substances act at different rates, the least plentiful usually acting the most rapidly. Carbon, phosphorus, and potassium go through cycles of adventures, while silica and most of the silicates are slow of change and reaction. The only constituents of the earth's surface that are plentiful, and at the same time show visible and calculable changes, are carbonate of lime and the iron compounds. Thus Mr. Goodchild would recommend a close comparative study of the iron ores of the world from his standpoint, including those in Cumberland, North and South Spain, India, Brazil, and Lake Superior. That such a study would meet prodigious obstacles cannot be denied, for direct evidence would be scarce, and often almost unrecognizable, and until some evidence of this growth of land is obtainable many scientists and practical men may as likely as not refuse to believe in its importance. For ourselves we keep a receptive mind ready to consider any proposal put forward by a serious and competent student of nature. These chemical forces acting on a large scale as outlined by Mr. Goodchild would provide explanations for many phenomena which are at present obscure, and they would afford alternative explanations for others. For instance, banded ironstones and doubtful gneisses would be explained ; the apparently igneous rocks which look like sedimentaries, or vice versa, would be relegated to their proper division ; an explanation would be provided of the absence of metamorphism at the contact of certain supposed igneous intrusions ; it would no longer be necessary to attribute schistosity or slatey cleavage to enormous pressures, nor contortions of rocks to the folding or crumpling of plane deposits. Sulphur would cease to be essentially a hypabyssal element, and pyrites would be usually formed by the action of iron compounds on organic substances. The current principles of petrology may appear to stand in the way of some of the foregoing applications, particularly where a doubt is implied of the igneous origin of certain rocks ; but that remains to be seen. However, we are travelling a little too far in advance. These prospective explanations are merely given as an indication of incentives to investigation on Mr. Goodchild's lines.

REVIEW OF MINING

Introductory. Though coal mining has been resumed for over a month in this country general trading is still stagnant and the prices of industrial metals continue at a low ebb. As for gold, the United States Exchange has dropped again, and the premium has correspondingly risen.

Transvaal.—The labour question has been to the fore this month, and definite proposals were made by the Chamber of Mines for a cut in wages. The men have agreed to a standard of wages based on the cost of living, and this involves a reduction of 1s. 6d. per shift immediately. It is felt, however, that more than a cut is wanted, and that a weeding out of disaffected incompetents would do much more good.

Further particulars are to hand from South Africa with regard to the stoppage of sinking at No. 2 shaft, West Springs. It is now stated that this shaft had reached a depth of 3,000 ft. without having encountered the Kimberley slates, which were expected at a depth of 2,300 ft. to 2,400 ft. A big transverse fault-plane is known to traverse the Springs property, and No. 1 shaft is near this line of disturbance. No doubt this dyke has had a disturbing influence on the country round No. 2 shaft.

About eighteen months ago additional capital was subscribed for the reopening of the Sheba Gold Mining Company's properties at Barberton. Since then much prospecting work has been done. The mine that has responded best is the Zwarzkopje, where 14,603 tons averaging 10·4 dwt. gold per ton has been proved. At the Intombi section the reserve is 20,000 tons, averaging 10 dwt. Further development is to be done before milling is recommenced, and when that happens it is intended to add tube-mills for the purpose of grinding the ore finer.

Rhodesia.—The output of gold in Southern Rhodesia during June was 49,466 oz., as compared with 48,744 oz. in May, and 45,054 oz. in June, 1920. Other returns of output for June were as follows: Silver, 13,243 oz.; coal, 49,425 tons; chrome ore, 5,831 tons; copper, 264 tons; asbestos, 1,993 tons; arsenic, 48 tons; mica, 7 tons.

The Lonely Reef Gold Mining Company reports the ore reserves at June 30 at 197,704 tons, averaging 19·11 dwt. gold per ton, as compared with 202,845 tons averaging 20·8 dwt. at the end of December last.

There appears to be some chance of a deal being effected between the Globe & Phœnix and the Rhodesia Exploration Company (formerly Amalgamated Properties) with regard to the John Bull and other claims round which the celebrated lawsuit centred. The chairman of the latter company has announced that he is in negotiation with a director of the Globe & Phœnix, but whether officially or not is uncertain. The Globe & Phœnix reserves at June 30 were calculated at 89,491 tons averaging 30·39 dwt. gold per ton, as compared with 93,852 tons of similar tenor six months previously.

West Africa.—The Ashanti Goldfields Corporation announces the intersection of the Obuasi lode at the 19th level. Here the lode is 26 ft. wide and averages 19·9 dwt. of gold per ton.

Australia.—The reports of several companies operating at Kalgoorlie are quoted elsewhere in this issue. These companies are now securing full benefit of the gold premium, and are thus able to earn increased profits. But gold premium does not account for all, and in this connexion we may express our pleasure that Mr. J. A. Agnew drew attention to the excellent management of the mines which is also a substantial factor in the present position. Too often most of the directors and all the shareholders omit to give any real credit to the mine managers for the satisfactory results; they even begrudge the few minutes occupied at the end of a meeting when a perfunctory motion of thanks to the staff is introduced, for this item of the agenda unnecessarily cuts into their lunch.

The cabled report of the Hampden Cloncurry Copper Mines for the half-year ended February 28 shows a yield of 1,882 tons of copper, 1,149 oz. gold, and 7,256 oz. silver obtained from the smelting of 36,698 tons of ore, of which 4,065 tons was custom ore and 9,391 tons metalliferous flux. The operations resulted in a loss of £6,694. As already recorded the properties and the smelter are now idle, awaiting a reduction in wages and in the costs of stores.

During the year ended May 29, the ore raised at Mount Morgan totalled 260,062 tons, of which 89,405 tons was sent direct to the smelter. At the concentrator 167,802 tons of ore yielded 60,033 tons of various classes of concentrates. The smelter treated the ore sent direct, together with 19,129 tons of

jig concentrates and 32,667 tons of table and flotation concentrates. The yield of copper was 5,149 tons, and of gold 76,463 oz. It has not been possible to declare a dividend. At present the labour position is uppermost, and the directors are endeavouring to induce the men to adopt some scale of wages that will make it possible to operate without loss. The company is actively developing and equipping a coal mine at Baralaba for a capacity of 500 tons per day. Experiments are in hand for chlorinating the tailings from the concentrators with a view of saving further quantities of gold.

The Governments of Great Britain and Australia continue to refuse information as to the price paid by the former for Australian zinc concentrates. The Board of Trade states that the total sums disbursed for the years ended March 31, 1919, March 31, 1920, and March 31, 1921, were £1,221,859, £490,137, and £151,951 respectively. It is also announced that concentrates totalling 4,972 tons have been sold at an average price of £7 17s. per ton. Presumably this is the sum of the sales all these years. Their deal has not been good business for anybody except some of the producers at Broken Hill, and even these will eventually suffer owing to the large Government stocks standing in the way of a revival in mining.

India.—Champion Reef will be the next Indian mining company to reconstruct with the object of providing funds for further development in depth. Mysore and Nundydroog have already reconstructed, but Ooregum has been able to provide funds for the same purpose out of its rich ore reserves. The directors believe that the ore disclosed in the lowest workings justify deeper development, so a scheme for raising the necessary capital will be submitted to shareholders next month. It may be mentioned that the shaft in Carmichael's section of this mine is over 6,000 ft. deep on the dip.

Burma. — The Burma Corporation announces a reconstitution of the London Committee, which now consists of Sir Henry Strakosch, Sir John Mann, and Messrs. J. A. Agnew, A. Chester Beatty, F. A. Govett, Herbert Guedalla, and J. C. Prinsep. Mr. E. P. Mathewson is to visit the mine and advise on the metallurgical position.

Malaya.—The report of the Federated Malay States Mining Department for 1920 shows that 34,938 tons of tin concentrate was exported; of this amount 22,134 tons came from Perak, 8,851 tons from Selangor, 3,252 tons from Pahang, and 697 tons from Negri Sembilan. It is stated that 64% of the mines were under Chinese management, as compared with 68% in 1919, and 74% in 1913; it would be much more interesting if the relative percentages of output by Chinese-managed companies were given.

Cornwall.—The respective boards of East Pool and South Crofty have not yet been able to find a basis of joint action in connexion with the unwatering of the mines. After the pumps at East Pool main shaft were put out of action by the collapse of ground, pumping was continued at Agar shaft for a time. This pump has since been stopped, but owing to the dry season the water is not rising rapidly. The board of East Pool have now in consideration a scheme for sinking a new shaft, at a point situated to the north-east in the Tolgus section.

Shetland Isles. — For the benefit of numerous readers who have sent inquiries relative to a paragraph in the last issue we record herewith the formation of a company called the Sand Lodge Mine, Ltd., with a capital of £100,000, to acquire property from the Shetland Exploration Syndicate, in Sandwick and Cunningsburgh, on the Mainland of Shetland. The new company is housed with Murrietta & Co., Ltd., 19, Great Winchester Street, E.C., and Dr. J. R. Garbe is the consulting engineer. We await the publication of a report on the property by a mining engineer of recognized position.

Canada.—The Kirkland Lake Proprietary Company is taking steps to increase the scale of development on its properties, the Tough-Oakes, Burnside, and Sylvanite. Mr. S. C. Thomson, of New York, who was at one time consulting engineer to Messrs. S. Neumann & Co., in South Africa, has been appointed consulting engineer to the Kirkland Lake Proprietary, and it is also understood that Mr. W. H. Goodchild is to be sent out to make a geological study of the properties. In this connexion it is of interest to read what Mr. Reginald E. Hore has to say in the *Canadian Mining Journal* with regard to the prospects of the Kirkland Lake district. He strongly recommends the resumption of surface prospecting on a systematic scale by stripping the overburden. He is of opinion that continuity of the deposits in depth may be expected and that liberal expenditure on development and underground prospecting is warranted. He

specifically mentions the Lough Oakes, where he recommends a search for the continuation of the ore-body which was cut off by faults both laterally and in depth.

United States.—The proposal to place an import duty of 35 cents per barrel on crude and one of 25 cents on fuel oil has not been received with approval by the Government. The House of Representatives struck the clause out of the Tariff Bill, while President Harding has issued a message declaring that such an action would be entirely opposed to the present policy, which seeks an open door for the United States in all the oil-fields of the world.

Mexico.—The politics of the oil position is intimately interwoven with United States interests and the battle is between the American oil controllers and the Mexican Government. The American producers who recently suspended operations as a protest against the increased export tax have decided to resume operations.

Alarming reports were spread last month with regard to a fire in the Amatlan oilfield. Fortunately these reports proved to be greatly exaggerated, and it appears that only four wells were involved. The properties of the Mexican Eagle company were not damaged in any way. In fact, the engineers of that company did much to bring the fire under control and prevent it spreading.

The following figures for the output of base metals and minerals in Mexico during 1920 are given by the Financial Agent in New York of the Mexican Government :—

	Metric Tons.
Lead	82,517
Copper	49,192
Zinc	15,650
Mercury	75
Manganese	1,137
Antimony	622
Tungsten	40
Molybdenum	4
Arsenic	2,091
Graphite	3,222

There is nothing to indicate whether these figures relate to metal extracted, metallic contents, or ores.

Venezuela.—The reports now issued as to prospects at the South American Copper Syndicate's mine at Aroa are distinctly encouraging. The diamond-drill campaign has proved the existence of a new ore-body of obvious importance, and this method of exploration has been fully demonstrated to be the right one for ores of this sort, that is to say, copper sulphide deposits in limestone. The new smelting plant is ready to start whenever the power plant is completed.

Colombia.—At the meetings of the Nechi and Oroville Dredging companies, Mr. J. A. Agnew gave some particulars of the method of realizing the gold produced. This information supplements the remarks on statistical returns published in the July issue of the MAGAZINE. The gold produced by the Nechi and Pato companies is shipped to New York for realization, and the mining profits transmitted from New York to London receive the benefit of the gold premium. For some time the companies were not allowed to export their gold from Colombia, and even now it is not possible to ship it as coin or bars. The companies, however, found that it was possible to ship it as sponge, and they go to the inconvenience of putting it in this form. It will be seen from this explanation that the periodical outputs are given in United States currency and that the benefit of the premium comes in the remittance of profits from New York to London.

Spain.—Some perturbation has been caused among the English and other foreign mining companies operating in Spain by the issue of a royal decree preventing the holding of mining property by any companies other than those of local domicile, which must have both chairman and managing director of Spanish birth. Apparently this decree affects only new ventures or expansions of operations by present companies, but this point is not clear. In any case there is some doubt whether such an important change could be made by royal decree.

The Pena Copper Company raised 82,751 tons of ore during the year 1920, of which 43,161 tons went to the leaching floors. The precipitate obtained contained 516 tons of fine copper. The shipments of ore were 6,181 tons of cupreous ore, 24,271 tons of sulphur ore, and 93,582 tons of washed ore. The net profit was £34,645, which was carried forward.

Siberia. — The Ayan Corporation, Ltd., has been registered, with a capital of £300,000, to acquire alluvial gold properties on the Okotsk Sea, north of Nicolaievsk, and certain trading interests. Mr. C. W. Purington is the pioneer who has introduced this business, and he is supported by many companies identified with the Lena Gold-fields.

LAND GROWTH

By J. H. GOODCHILD

The Author outlines a method of approaching the main problems of geophysics and geochemistry.

In the April issue of the MAGAZINE a letter of mine was published, contributing to the discussion on iron ore in Cumberland. An editorial article in the same issue referred to views and arguments, leaving readers to discover that the main point of that letter was an appeal. The suggestion was made that argument should be suspended while a comparative study of iron ore regions is undertaken. The aim would not be the origin of the ore so much as a critical study of the surroundings, taking all that the iron suggests as an aid to imagination and expression. That letter and the editorial note may serve as an introduction to the following sketch. In such an irregular piece I beg that I may be excused the giving of references or making acknowledgments. It is all acknowledgment. The world is full of ideas of the kind. At the same time, for the better understanding of some allusions I must mention Professor D'Arcy Thompson's *Growth and Form*. It is no use for me to try to imitate his treatment, but it could undoubtedly be followed in the places considered. Further, those who can should refer to the following :—

(1) " A Brief Summary of the Theory of Isostasy," by Colonel Burrard. *Geographical Journal*, July, 1920, noting particularly the remarks of Mr. R. D. Oldham.

(2) " The Interior of the Earth," By Mr. R. D. Oldham. *Geological Magazine*, January, 1919.

(3) The first chapter of the second volume of *The Face of the Earth*. Ed. Suess, Oxford edition.

The exhaustive study of *The Manganese Ores of India*, by Dr. L. L. Fermor, nominally an official production of the Indian Geological Survey, and the writings of Dr. Morrow Campbell on Laterite, have been the most instructive, not to say inspiring, literature on tropical geology which has come my way.

* * * *

The elevation and depression of the land, or as Suess prefers to name the problem, the displacement of the strand line, is discussed in his second volume. The first chapter gives a history of ideas regarding it. He records that in A.D. 1320 Dante delivered a discourse " De Aqua et Terra." At the time it was generally held that there were two centres, about which the elements ranged themselves in symmetry, one for the waters of the ocean and another for the land, and these were so placed that the sea was higher. Did not the land sink below the horizon as a ship put out to sea, and was last seen by the man on the mast ? The greater height of the sea accounted for the occurrence of springs near the summits of mountains.

Dante showed that all this was untenable. Water condensed on the mountains from the atmosphere and would thus produce springs. He gave his reasons for rejecting the two centres, saying that it is evident that the land rises from the ocean owing to particular elevations of its mass, and not as a result of a general eccentricity, since in the latter case the dry land would be bounded by a circular outline, and this we know is not so. He goes on to say that the earth cannot raise itself, nor can the cause be water, air, or fire ; the elevating force must therefore be sought in the heavens.

Dante thus adopts the system which had already been expounded in greater detail by Ristoro d'Arezzo in 1282 ; according to this, not only must the irregularities of the earth's surface be ascribed to the fixed stars, but mountains and valleys present, as it were, a mirror of the various distances of these stars from the earth, in an inverted sense, like the impression of a seal in wax. In addition, Ristoro is aware of the erosive power of water, and of the existence of fossilized remains of marine animals.

Let us suppose, then, a man of that time contemplating the mountains of Italy. He sees them as particular elevations. Tradition and habit favour the view of each mountain as a separate entity with its name, but there is also probably a word like " monte " in use for high, barren land in general.

He has seen the tops of these mountains snow-capped in winter, the snow disappearing in the spring. The water sinks into the ground or runs away over the surface. In the first case, a source for springs, in the latter a force tending to develop form by cutting out ravines.

But, besides the evanescent snow, there lies on some mountains something more stable yet often curiously like patches of snow. It is, when you come near it, a whitish soft stone. It contains shells like those found in the sea. What can this mean? The sea! Wonderful thought! Could the mountain have been below the sea? Could these creatures have been buried as travellers sometimes are in a snowstorm? Could this greyish-white stone fall, settle on the mountain, harden and set like mortar? Some patches are much higher than others. And if some power did lift the mountain with this load to the upper air, how should it not bend, break, be drawn out into streaks and veins as we so often see. The outer form

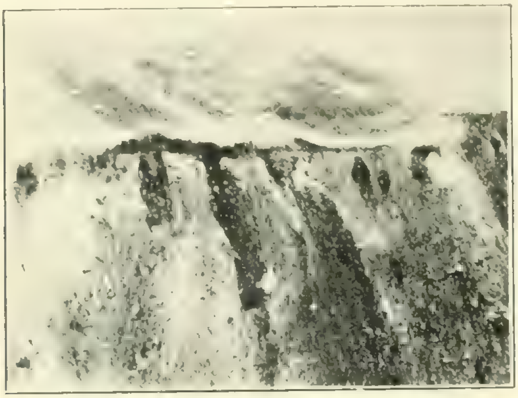

Fig. 1.—Typical Chalk Pipes.

is all jagged and scarred, and more than this, the entrails are as though one should draw out dough or clay of different colours as the potters do. And the water in the caves drops crystal! Here is no sign of water at a higher level in the sea rising through the earth. The high power we must invoke seems above. It lifts, it lifts the mountain! No, not the mountain. There is lifting, there is a drawing out, and the mountain grows to its present form as all comes up through the salt water towards the rain and cloud. Even as the snow melts, so this lime with the shells melts. Part goes through the mountains and part lies in hummocks on their sides.

*　　*　　*　　*

This was before the day of "crust," before it was easy to speak of a globe with an interior, before there had been added to all the other influences present in observation and description tending towards the choice of words like "rock" for a fraction of the crust, the additional influence of palæontology.

Our feet inform us that the ground is solid. Twenty miles of solid is solid. Then, compared with the fossil, the "rock" was a tombstone, a tablet in a record. Building-up went by rock-forming. There were *agents* which formed and destroyed. Rock by comparison was patient, not agent.

*　　*　　*　　*

Yet there is, of course, plenty of activity in the hills. Consider the elementary case of a chalk-pipe, one of those iron-stained shafts or pockets which so easily catch the eye in the south-east of England, where

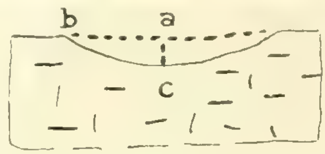

Fig. A.

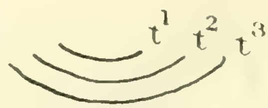

Fig. B1.

Fig. B2.

gravel and sand lie on the Chalk (Fig. 1). These pipes were considered formerly to be perhaps filled pot-holes. The flints and sand are in a "hole" in the chalk. How did they get into it? By being swirled in with water. The pipes, however, are often highly symmetrical, and Prestwich, in 1855, discussed at once their symmetry and chemical origin. He said that probably solution of the chalk took place at favourable spots, sand and flints flowed downwards, a cylindrical

shaft being formed and filled continuously. As regards the form, he thought that a pipe begins as a basin-shaped depression with depth *ac* less than radius *ab* (Fig. A). As the growth proceeds these proportions are not maintained, solution being more rapid at the bottom than at the sides, that is *ac* becomes greater than *ab*.

The pipe, therefore, does not enlarge with time, as in Fig. B1, but as in Fig. B2. It is probable that the internal processes of this cell-like growth are complicated. Very likely the iron counts for something more

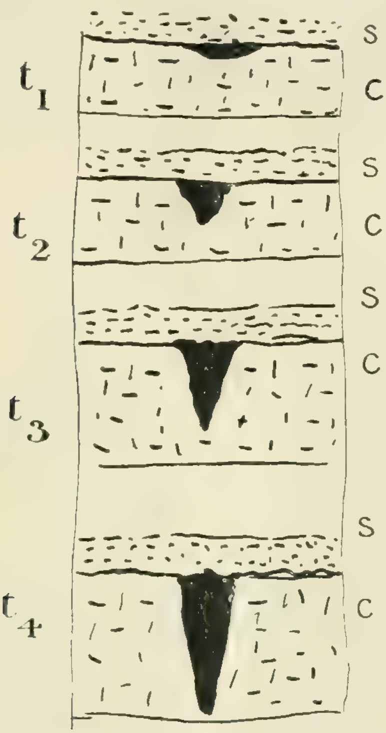

Fig. C

S = Sand C = Chalk

than an adventitious stain. Simplifying the processes, we may suppose that iron and organic matter come from the overlying sand, and so

Organic matter + iron as catalyst + oxygen + water give CO_2 + water + ferric compounds.

Ferric compounds have an affinity for silica, and tend to be retained by it as well as by the alkaline reaction of the chalk. The rhythm of the seasons may enter into the processes, leaching and diffusion being more rapid in wet weather, dry weather favouring some other necessary phase.

In any case, you have a symmetrical external form growing by balanced complicated processes within. A new thing has been born, which has a behaviour as an individual, calling for a *name* by reason of its symmetry and definite character. Many are shapeless, however, and of all degrees of definiteness, due, no doubt, to lack of just the right balance in the factors. The shapeless ones are but as part of the overlying sand, and have no name.

Taking a symmetrical case, we can think of a " growing " or " dynamic " pipe, and represent momentary states as in the diagram (Fig. C). To these alone does the notion of " rock " or " deposit " seem to apply.

The reality over the interval t_1 to t_4 is a changing thing, or, at any rate, when we say that " it grows," we are using an ordinary and well understood notion.

If enough iron, organic matter, sand, etc., enter the growing cavity, action on the chalk and growth of some kind might be continued even if communication with the surface were cut off by the closing of the orifice from any collapse or thrusting movement. If water continued to penetrate, the enclosed materials would be as so much food to be digested, and the resulting equilibrium form at the moment t_n would depend on the rates of the various happenings internal and external during the interval. The growing pipe is a kind of cell.

The following points are briefly noted :—

(1) The *colour* of the iron first attracts our attention, then helps us to visualize possible changes, and on the large or small scale would assist in following them by *comparison* of different cases.

(2) Catalytic action of the iron probable and therefore a highly suggestive example lies before us under comparatively easy conditions.

(3) These pipes occur below such a formation as, say, the Thanet Sand. They are examples of internal change or interaction between two so-called rocks, which in stratigraphy are said to be of different " age." The *law of superposition* is thus called in question.

(4) When equilibrium is reached the cell appears as a low order of *concretion*, but during growth it might be said to function as a low order of *agent*.

* * * *

Having visualized the pipe, or cell containing sand and iron, growing into the

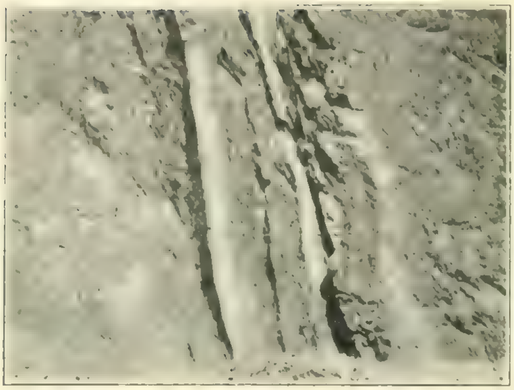

Fig. 2.—"Gashes" and "Faults" in a Calcareous Shale.

Chalk, we remember that the water and products of reaction pass away into the latter. The Chalk also with its innumerable surfaces of interaction is a scene of internal change. That impurities should be able to segregate or come to equilibrium in this region of action and freedom is not more surprising than that water should collect in streams on the free surface of the hills.

The Chalk formation which covers so large an area of Western Europe is still a kind of sea, where freedom for growth and segregation obtains, although we walk on it as solid land and are therefore liable to forget or ignore these internal potentialities when larger questions are to be considered.

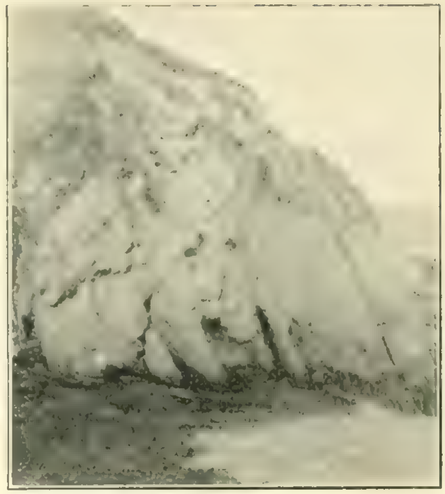

Fig. 3.—Thin-bedded Calcareous Shale near the Hill shown on the right in Fig. 5.

As the flints and sand adjusted themselves by falling to form a symmetrical cell, so the Chalk will adjust itself in "jointing" and "bedding," while solution and precipitation and other processes are taking place internally. Turning our thoughts back to the vastly greater accumulation which slowly covered the floor of the Cretaceous sea, we easily recognize that all subsequent happenings are to be related to a "dynamic chalk," something changing internally at

Fig. 4.—Massive Limestone among Calcareous Shales, Basque Country.

FIG. 5. MINING DISTRICT OF BILBAO.
Large masses of iron ore are quarried on the hilltop to the left where the limestone visible in the centre is faulted down. To the right, the valley is in less resistant shale. The conical hill has a backbone of limestone. Dykes and indefinite masses of greenstone are found in all directions but are of small dimensions.

appreciable rates. The flint veins or marcasite nodules could grow in such a medium as freely as on the open floor of the sea. No open fissure is needed for the flint vein, but at the same time " replacement " may be an expression liable to mislead. It is a reversion to the idea of a fixed place or thing to be replaced.

If so large a quantity of matter pass from solution to the solid state, from sea-water through the organisms to the great " beds " on the floor, when we recognize that these are anything but constant or enduring, are, moreover, chemically active, we are led on to grasp an idea of " growing land," something not merely piled up, consolidated, and afterwards eroded. By way of the sea, in this case, the land assimilates a vast quantity of material, which will continue to function. The land is by so much the less " dead as a stone ", the more a living body.

If Chalk lying between Greensand and Thanet Sand is a field for the growth of pipes, so the Carboniferous Limestone in Cumberland is a field for the growth of hematite. The pockets of hematite are often found below the limestone, so before forgetting the Chalk and the sand cells on its

FIG. 6. TYPICAL LIMESTONE REEF IN BASQUE COUNTRY.

upper surface, we may find similar tendencies on a lower or on any surface. [illegible] flints and sand falling down, insoluble matter or compounds being precipitated might be squeezed up or in any direction. The percolating water might take any course, but the growth of the resulting cell would not necessarily be in the same direction The squeezing of creamy clay following on solution of limestone at a contact with an aluminous rock would probably be accompanied by osmosis, diffusion, etc., and these factors would determine according to their values the precise nature of the resulting growth. Particularly a sharp separation of crystalloid from earthy substances is likely. Some of the resulting growths might be vein-like, or, in dyke form, the crystalloid compounds moving at different rates from the earthy. In other cases the segregation would be widespread and fairly uniform, partly governed by lines of bedding determined during mechanical deposition in water.

* * * *

In photo No. 2, from the neighbourhood of Bilbao, in the north of Spain, are seen "beds" of "greensand" in a calcareous shale, somewhat like our Gault, but harder, and belonging to a complex of about the same age.

Photos Nos. 3, 4, 5, and 6 give an idea of the country. As one walks these valleys one passes through the depths of an ocean bed. Since the day when the coral reefs rose and sank, were silted up and buried, a vast field for internal action has passed from saltwater conditions to freshwater conditions.

The great masses of limestone and all the disseminated carbonates in the shales and marlstones, now dissolving and creating cells or tissues for complicated changes, are representatives of potential action and instability. Such a complex could conceivably imbibe salts from sea-water and deal with them after the manner of a plant. I cannot say whether glauconite occurs, but many of the beds, such as shown in the photograph (Fig. 2), are like our greensand.

Photo No. 7 shows a dyke which is one of many related to the ophitic dolerite masses common throughout the region. Such dykes are commonly called "intrusions," yet along with these two types of greenish silicate rock, one describable as a bed, and the other suggesting the injection of molten silicate rock, there are numbers of indefinite bodies consisting sometimes entirely, sometimes only partially, of alkaline silicates. Some lie along the contact of limestone and shale, some are mixed with siliceous sinter or flint in lenses.

Taking the district by itself all the suggestions are in favour of growth within land accumulated in the Cretaceous ocean, resulting in the segregation of dolerite, trachyte, and ferrous carbonate. If some of the "greensands" are like the "greenalite" of the Lake Superior region, there seems no need to suppose volcanic exhalations accompanying sedimentation to account for their silicate composition and bedded form, as Van Hise suggests. The open space or freedom sought in such speculations is potential here through the solubility of a large part of the system.

In looking at the great masses of limestone either pure or marly, we can conceive of equal quantities slowly vanishing; the vanishing mass in its surrounding clayey envelope would be as it were a vast cell for processes of growth within. We may suppose that something of the kind is going on now in the Pacific round about coral reefs. At the same time we cannot expect that the more unstable substances would remain. Chlorides would be washed out. The evidence of the iron mines suggests that carbonaceous matter has been an important factor.

It is not surprising that in the early nineteenth century, while the notion of "rock" was strong, and there was no immediately apparent agent for the production of these internal greenstones, the volcano and the interior of the globe should be invoked.

It was a service to stratigraphy, tectonics, and palæontology to clear chemistry out of the way by a plausible theory. Externally formed beds invaded by "igneous" dykes, from inside, left the road open for rocklogic and mapping. We reap the reward of the statistics recorded in all parts of the world in a language which had two plain, easily understandable species as basis, the inside "igneous," and the externally accumulated in a free space, the "sedimentary." Intermediate varieties, difficult chemical complications had to be made to fit in or be ignored. Volcanoes could be observed, sedimentation could be observed, but chemical changes in "rock", though often suggested were too recondite, too difficult to observe for any compelling or

consistent body of evidence to be obtained concerning them. To-day so much has been done in other fields of inquiry that the attempt to treat such a region as this of Bilbao as "growing land" would not meet with so many obstacles, and it would be worth while to concentrate on this vast concretion, of which these two or three little photos give some idea. It is just the indefinite things which are so hard to record, and I have none to show.

Needless to add, French and Spanish geologists, as well as some British, have paid a great deal of attention to the "ophite," and endeavoured to shake themselves free from the incredibilities which the only available descriptive language tended to impose (Fig. 8).

Fig. 7.—[illegible]

*   *   *   *

The scale and character of possible chemical changes can be the better imagined by considering the ground opened up in mining the large iron deposits. In and about the limestone occur deposits of siderite with oxidized outcrops. Many of the quarries have removed most of the brown hematite and are down on the carbonate. Unfortunately no adequate photographs were available.

A simple theory of the origin of the ore is to suppose that at some period since the limestone masses were coral and shells poor carbonate of iron with intergrown calcite began to concentrate. There was oxidation later, giving brown, red, and purple hematite, enrichment of the carbonate below to pure siderite, which again in turn oxidized to hematite. The details, however, are complicated, and the main interest for the moment is the fact that mining reveals so much clayey decomposed ground, with evidence of slumping as in the case of the chalk pipe, that having these things to refer to in the same region as the greenstone dykes, the *general* idea of growth with unstable and chemically active limestone as a factor is well sustained. Neither the *source* of the iron nor the *source* of the alkalies in the silicates is at first of great importance until we have given full scope to this idea of *growing land*, and are ready to criticize "beds" "faults," "folds,"

Fig. 8.—[illegible] BEING PART OF THE PERIPHERY OF THE MAIN MASS OF TRACHYTE IN [illegible] MILES AWAY

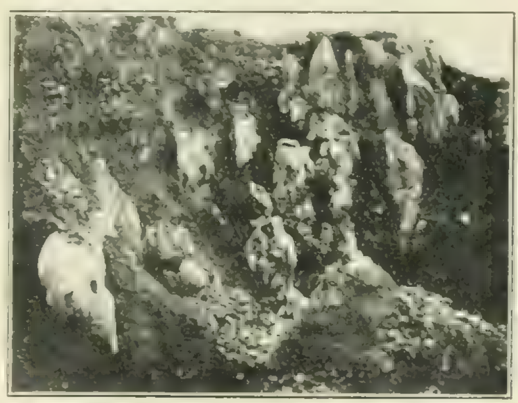

Fig. 9.—[illegible] GROW IN BETWEEN THEM

"intrusions" etc. The growth is so well illustrated by the iron deposits, and is as much to be attended to as a volcano or a river depositing sediment.

* * * *

Consider one superficial feature shown in photo No. 9. On the hard limestone lies loose earth full of brown hematite grains and nodules. The undissolved pinnacles ("dolomias") are left, showing a rhythmic advance of solution in a vertical direction. The pinnacles are often wonderfully symmetrical. In the top right-hand corner of the picture will be seen two or three of them sharply pointed, straight-sided. Far better groups exist than those here shown. The apices are conical and the sides have broad re-entrant flutes. Here there is rhythmical grouping of symmetrical cells between symmetrical pinnacles, the direction of growth in the vertical being determined by gravity. Within the loose earth the grains and nodules follow their own habits, and it is a question whether the presence of the iron has not something to do with the nicely balanced advance into the limestone, so as to produce the symmetrical pillars.

We found that a single chalk pipe, when symmetrical, called for a *name*, but I have never heard of a name for a *group* of pillars and cells, such as these. Suppose, now, instead of this coarse cellular growth in a vertical, gravitational field, some similar chemical reactions took place where everything slipped or were drawn out in long lines, the group of cells would become a tissue. Such a tissue would be fissile, cleaved, or foliated, and would call for a name such as shale, slate, or schist. These names are integrations of a property common to the whole mass; they are like summations, and somehow this summing of a series in naming works itself into our reasoning about the formation or behaviour of the tissue. That is to say, unconsciously in observation, description, or argument there is implied that the whole sum of the parts was formed by an *adding* together of the parts. These pillars grew simultaneously, and the laminæ of many shales, slates, and schists of complicated composition grew simultaneously by complicated internal processes. Of course, the textbooks warn us against confusing stratification or bedding with "cleavage", but almost on the next page the writer will probably use an argument about a "slate" which would only be valid if the cleaved layers had been added together. It is easy to imagine branching veins of quartz or pegmatite found running through a slate being formed as an excretion or as part of the growth of the tissue, so that the inference of intrusion or injection or percolation of solutions in fissures is unjustified.

Another noticeable point in connexion with these pinnacles with their pockets of earth and iron nodules is the appearance of crystallized calcite on their sides, something like wax guttering down a candle (Fig. D).

Fig D

That is to say, at some period during the growth there appears to have been a sort of reversal or halting between two alternatives on the part of the dissolving $CaCO_3$. Either solution and disappearance or recrystallization on the side of the pillar. Anyhow, it is easy to conceive of recrystallization spreading over the whole field, enclosing the nodules of iron ore, though during the process the iron might well be dehydrated and appear as brilliant flakes. The end result would be a saccharine or crystalline marble with red or black hematite streaks through it. The main point which is certain is that iron and calcium carbonate are *on the move together*.

Where large quantities of the one, the $CaCO_3$, are disappearing from the field altogether there will be forthcoming the freedom, the potential open space, for growth into permanent equilibrium forms. Such a complex might be called a "rock" or it might be called two or more rocks, depending on how the whole growth had proceeded. The symmetries developed sometimes tend to be grouped into one, so that a compound hematite-calcite rock is considered as one species. Or they might be of such a nature that the iron ore would be considered separately as a "lode" in a crystalline limestone.

The earth in the cells must not be forgotten. In the recrystallization of calcite and hematite insoluble matter would have to pack itself away between the more mobile substances.

* * * *

Intergrown red hematite and calcite showing that these two substances at least

have been on the move together is well illustrated by deposits in the province of Zaragoza, Spain. The type of ore closely resembles Cumberland hematite, and it occurs where Triassic and younger formations overlie slate or quartzite marked Silurian. At the particular spot I have in mind it seemed impossible to find any boundary between the red and green Triassic rocks and those said to be Silurian. Further, it may be remarked that in this rough and arid region, where at first the mind might be predisposed to the solid rocky view of things, the finding of soft wet hematite below ground, mine waters turbid with red oxide and depositing calcite at a great rate, is a notable contrast. When these facts have been weighed the crystalline limestones on the hillsides, with their wavy lines of hematite and curious enclosed nodules, are recognizable as probable growths within, as products of the mingling of substances from formations of different age. It is natural to ask how far such action has affected the whole region of slate and quartzite, and where chemistry is concerned what weight to give to unconformability.

Fig. 10.—Iron Quarry in Sierra Nevada.

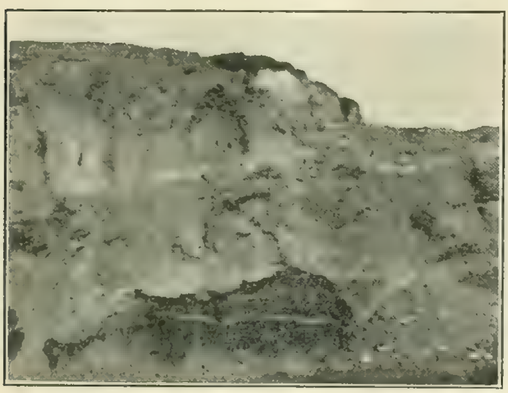

Fig. 11.—Iron Quarry in Sierra Nevada.

In the cases of the chalk pipe and the pinnacles growth occurred in a "solid" medium, or advanced through a field filled with solid. There was not the freedom of open water or of molten magma, but there was the less apparent though equally effective freedom of the unstable chalk or limestone, solid for the stratigrapher, solid for walking on, but potentially not solid when growth is being considered. So by these banded crystalline hematite-bearing limestones we are brought a further stage in grasping what changes are possible in solid-seeming, hard, dry, rocky land.

Fig. 12.—A Wady in the Sierra Alhamilla.

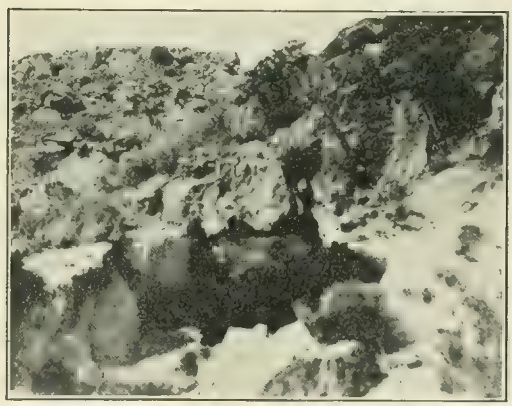

Fig. 13.—Limestone (Triassic?) lying on or in the schist shown in Fig. 12.

The action, however, has been local and incomplete. Where there has been less action the "sedimentary" strata are recognizable; but supposing it more complete and widespread, the end would have been a "metamorphic" area.

* * * *

Photos Nos. 10, 11, are from the Sierra

Nevada [illegible] near the Mediterranean coast of Almeria. The area is marked on the Spanish maps as "Estrato Cristalino," indicating a careful and philosophic reluctance to use the word "metamorphic." There are remnants of Tertiary and Triassic strata scattered over or enclosed in schists, slates, and crystalline limestones.

In the quarries shown the main mass of rock is a soft, unctuous schist, more or less "decomposed", accompanied by limestone or dolomite varying greatly in colour and texture, with splashes of hematite even more varied. The hypothesis or expression "replacement of the limestone," which serves well in Cumberland, has its weakness revealed here. It is so obvious that there is nothing fixed to be replaced. Everything is on the move, and photo No. 10 is eloquent to this effect. Notice the corner on the left, where the men and trucks are standing. From here upwards, towards the right, the dark streaks of ore are like clouds floating away across the face of the quarry, and at this particular spot there is no limestone visible; it is practically all soft schist containing these "clouds."

In No. 11 the dark mass at the bottom is purple hematite in a bed-like form, with two partings of white clay running through it. The vertical streak of white is only mud washed down the face. Notice also the sky-line. There is just an indication of the surrounding half-desert, dry, rough, and stony. Yet, not many feet down, water is encountered, with soapy rock, ready to slip and shear the while chemical change takes place in the moving medium. The ore below is mostly friable, porous, brecciated, but on the surface, of course, harder and frequently bespangled with calcite as though a sponge of hematite had been reimpregnated with calcareous solution and dried.

Everything, ore, limestone, soapy schist, wetness below, dry exterior, betokens collapse or yielding to external stresses accompanied by internal change. Most probably vast quantities of calcium carbonate and we know not what other substances besides have been leached out. During this leaching the oxide of iron has come to its present state of equilibrium, showing by the great variety of its textures and colours how sensitive it is to varying conditions. It varies from brilliant blue-black oligist to purple, brown, or yellow, more earthy forms. Needless to say that these two little pictures would require to be supplemented by hundreds of others in order to represent fully the characteristics of this region. The oxide of iron, more a dye and less a mineral, impregnates almost anything, but again seems to leave things untouched, to withdraw itself and concentrate. Note the bleached partings of white clay in No 11. Everywhere, however, the same lesson emerges, namely, that the presence of the iron makes clearer what kind of changes we have to bear in mind in considering such a region. Not only are iron and carbonates on the move as before, but siliceous materials are involved on a very large scale. The "schist" and "slate" can be imagined to be products of similar changes in less highly coloured siliceous materials. That many of the changes in the iron ore are produced by "weathering," and some of those in the schist probably deep down, need not abash us. In either case "growth" covers complicated "change of form," accompanied by "change of substance" or "metamorphism" and "metasomatism," combined and simultaneous. We are throwing away an opportunity if we neglect to make the comparison of the observable superficial deposit with those which may perhaps have grown or retain some characteristics of growth under deep-seated conditions. One suggestion is that the removal of vast quantities of matter, the carbonates, gives the *freedom* necessary for changes which are often ascribed to high temperature.

Let us now remark that these ranges of hills in this half desert region rise several thousand feet above sea-level, that patches of Tertiary strata occur at all levels, and that where the schists are exposed the remains of the Trias in many places look as though they were partly engulfed in them, and partly as though underlying schist were a sort of vertical fibrous filter on which the undissolved matter of the Trias has been caught, the soluble salts having entered into the reactions taking place in what is now schist.

You go up a deep gorge entirely in schist. Its sides show efflorescences of salts. The scanty wells often taste bitter. As you ascend to the tops of the hills you find hummocky limestone, occasionally gypsum, lying in disordered fashion across or tangled into the lines of cleavage. Photo No. 12 shows a gorge of dull-grey schist with quartz veins every few yards. No. 13 gives a rather poor idea of the limestone "caught on the filter," on the top of the hill above the

same gorge. There are signs of mingling everywhere. They are multiplied as soon as you go underground. What has happened in the vast complex which these hills represent, of which they are but the residue, since the Trias was laid down or since the Tertiaries were laid down?

There has been movement. What moved we can hardly say. Why it moved, much less. But how it moved and reacted we can in some sort make out from the present things.

There is every suggestion that in this region there has been movement through thousands of feet, and perhaps tendencies towards far greater distances never realized of materials partly accumulated in Triassic times, partly in Tertiary times, and that below the younger there has been mixture and reaction with the older, giving a streaking out into forms showing symmetries, producing this schistose complex. That these schists are Pre-Triassic or Pre-Tertiary is a statement to which it is difficult to attach any exact meaning, and for my part those "Pre-Cambrian" or "Archæan" complexes which I happen to have seen are to be looked at in the same way. How does the law of superposition apply to them? In the absence of fossils how do they come into the time scheme at all? That the Cambrian appear to rest on them means very little. Since life came to the world and calcareous matter was precipitated in large quantities in the sea, there has been a force at work renewed periodically from *above* which tends to destroy underlying things and their marks. The calcareous matter is, of course, not the only reagent at work, but it is in the observation of limestones that we are led to gather up the possibilities of internal change when unstable matter is engulfed or assimilated in the "solid" land.

Seventy per cent of the earth's surface is covered by sea. We saw in the Bilbao region that the remains of the Cretaceous there might give us some idea of the internal changes in the vast ocean bed, especially if we compared it with the Pacific of the present day.

Here, in this dry region of the south, where the very barrenness helps one to concentrate on the chemical aspect of things, where there is no antithesis of active vegetation or running streams to predispose the mind towards the solidity of rock, we are reminded by these lime-washed strata and have this reminder blazed out in colour by the iron, of the possibilities of mingling and growth in the land during its rise into mountain ranges.

In this same neighbourhood occur lava-like masses pointing to vulcanism. In the Sierra de Almagrera hot saline waters are pumped from the mines. That growth of the kind we are considering should sometimes result in violent reactions is quite easily thinkable. Salt, sulphur, or carbonaceous matter, which in other places owing to protecting influences have managed to survive as salt-beds, gypsum, or pyrites, coal or petroleum, if involved in such growth would increase the chemical potential to such a degree that local explosions might well take place. It must always be remembered that the known deposits of these substances are not quantitative samples. They are but indications of probable far vaster potential deposits, which, of course, would be the more likely ones to react with devastating consequences and their own obliteration.

* * * *

Photograph No. 14 shows the Tertiaries at Sorbas lying level in a break between the hills. They remind me of figures I have seen of the Indian Gondwana beds and their relations to the gneiss. It is obvious that isolated patches of a widespread formation may remain slightly changed while everything around may run together and produce new forms.

* * * *

If we are prepared to make the most of the phenomena of internal change, revealed in and about the mines of the Sierra Nevada region, the "estrato cristalino" becomes a kind of large concretion involving fragments of recognizable fossiliferous strata.

Those wonderful series which are so prominent in the tropics, under such names as itacolumite, Witwatersrand, Dharwar, can be viewed in the same way. They may be more perfect examples of "estrato cristalino."

* * * *

Photo No. 17, from Minas Geraes, Brazil, shows a typical outcrop of itacolumite, the famous "flexible sandstone." It is an oblique view of three parallel ridges with slate or schist between them. Close by is the well-known iron ore mass, the Pico do Itabira do Campo.

Photo No. 16 is a view of the eastern side of the Serra do Caraca. To the right, rising to 3,000 ft. above the plain, is the main mass of itacolumite. The double pointed hill

towards the left is chiefly of itabirite or hematite quartzite (Fig. 15). The plain is covered with "canga" or "lateritic iron ore."

Everyone acquainted with these regions knows that with variations such series occur over thousands of square miles, with granite or gneiss appearing at regular intervals.

In a paper entitled "Laterization in Minas Geraes, Brazil," published some years ago (*Inst. Min. Met.*, 1913-14) I gave an account of my impressions of this region. The line taken then was the same as I have tried to develop in this article. It was forced on me by the stupendous character of the "weathering" phenomena. The iron and manganese deposits bring out in such remarkable fashion the possibilities of growth that one is irresistibly led to universalize.

* * * *

A word about Lake Superior. I have never been in North America, but taking Professor Leith's word for it that the iron deposits are closely similar to those in Minas Geraes, make the suggestion that both may be Post-Cretaceous growths. That is, if it be possible to ascribe any age at all.

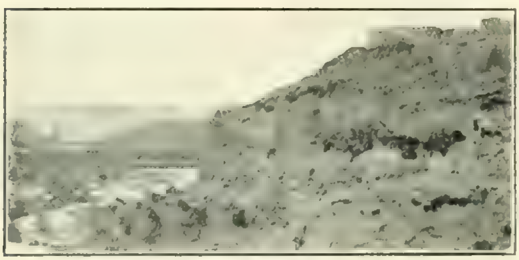

FIG. 14.—ITABIRITES AT SOBRAS LYING LEVEL IN A BREAK BETWEEN THE HILLS.

In India it has been found that underneath limestones there has been "replacement" of gneiss and other rocks. Further, there are the salt deposits of the Salt Range in Northern India, apparently Eocene, but from which it is said that the salt appears to have penetrated below the Cambrian.

My suggestion, then, with regard to Lake Superior and Minas Geraes is that since the time when these localities were in the "Pacific Phase," there has been a "drawing up of the mountain," a reaction between younger and older sediments. From this mingling and reaction is produced the "Atlantic Phase" of growth, with its crystalline rocks, its schists and banded iron ores in streaks. The deltas, lagoons, and submarine volcanoes which Van Hise professed to see in these streaks are, if I may so put it, an example of what rhythm can do in the imagination of able men, caught between a system of words and and the work of the "stars."

The freedom, the open space, required by lagoons and submarine volcanoes is potential in a system, solid for everyday thinking, but not to be thought of as solid when chemically active substances are for long

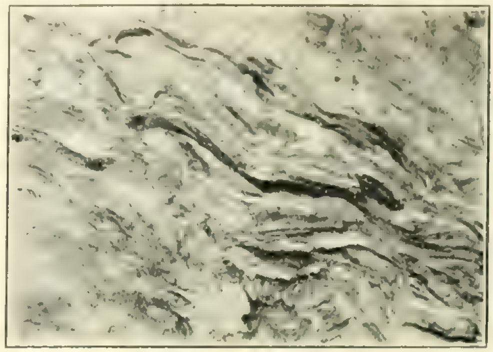

FIG. 15.—SECTION ALONG THE STRIKE OF BANDED ITABIRITE, MIGUEL BURNIER MANGANESE MINES, BRAZIL.

FIG. 16.—EASTERN SIDE OF THE SIERRA DO CARACA.

periods from t_p to t_a, in such relations as we saw obtained in the case of the sand lying on the chalk.

* * * *

We saw that the "chalk pipe" or cell helped us along with the consideration of physical and chemical changes taking place together, of falling related to solution, etc., producing definite symmetrical objects calling for a name, becoming definite members of a class or species. It led us to extend our range over great spaces to the conception of "dynamic" chalk, as a factor or agent or

organ in growing land. In a similar way, but in a way quite impossible for me to impart here, the hills of itabirite and their surroundings may brace a man up for the conception of growth on a vast scale in a system *represented* by the fossiliferous strata in places where this growth—this so-called metamorphism—has not destroyed the marks of origin. Such a "system" includes the sea-water and all other unstable elements as factors, and does not exclude, of course, influences from the interior of the globe, though since these

FIG. 17.—A TYPICAL OUTCROP OF ITACOLUMITE, BRAZIL.

are unknown they are regarded rather as factors in the "field."

*   *   *   *

Nearly all the great rivers of the world run off the Atlantic Phase to the Atlantic and Indian Oceans. Deposition of detritus predominates. To the Pacific Ocean few great rivers run down. There is a preponderance of chemical precipitation in the form of oozes and coral. When these latter are "raised" the more violent chemical or internal processes manifest themselves in vulcanism. The slower segregation of granite and the wearing down of the land until it appears as the Atlantic Phase has not proceeded to completion before the sea overtakes it, and detritus is again deposited.

*   *   *   *

Historically, at any rate, the so-called Basement Complexes of gneiss and granite are connected in thought with fusibility of alkaline silicates. It may be that we should give more attention to solubility, diffusibility, and all the suggestions which the biologist could supply as to the properties of potassium in particular. That granite and gneiss should be end products secreted downwards or tending in the main to be secreted within the land seems to accord with the known facts.

*   *   *   *

The foregoing notes and pictures are what I have to offer for consideration in connexion with a supposed organized undertaking appealed for in my letter. Readers of any experience at all will know that there is a time for logic and a time for faith, and will, I am sure, easily imagine what might be attempted on these lines by a joint effort to unify widely scattered local knowledge. My own belief is that a very wonderful and beautiful piece of work would result and that a new view of the life of land and sea is indeed opening out before us.

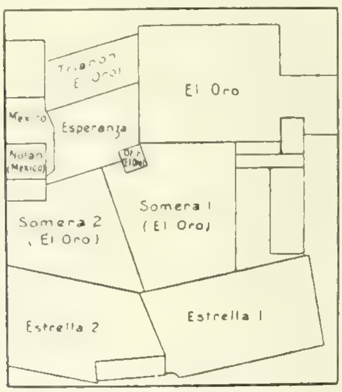
LAS DOS ESTRELLAS GOLD MINE

By T. SKEWES SAUNDERS, M.Inst.M.M.

The author describes a mine at El Oro, Mexico, of which he was manager for the last seven years. The control of this mine has been in France and Mexico, and details of the operations have not hitherto been available to English readers.

INTRODUCTION.—I have often been asked to give a description of the Dos Estrellas (Two Stars) gold mines at El Oro, Mexico, but occasion and opportunity have not been hitherto favourable. The following notes may help to complete the published information relating to an important gold-producing district of Mexico.

GEOLOGY.—Geologically the Dos Estrellas property pertains to the extensive belt of Cretaceous schists, known as the El Oro shales, that extend from the north-eastern part of the State of Michoacán to the southern part of the State of Mexico and northern part of Guerrero. These sedimentary rocks have been intruded by porphyritic rocks of Tertiary age, with the result that extensive faulting has taken place. Some of the faults follow the general strike of the veins—north-west and south-east—and are highly mineralized, thereby constituting profitable ore-bodies, as, for instance, the San Rafael vein in the El Oro camp; whereas other faults have a general easterly and westerly strike, but, although they affect the vein system in several ways, they are devoid of mineralization.



THE GOLD MINES AT EL ORO.

The Dos Estrellas Company has extensively developed a system of veins, the principal one being known as Veta Verde, which has ascending offshoots into the hanging wall, these offshoots, or branches, constituting in general payable ore. The main vein and all its branches occur exclusively in the shales and the whole shales as well as vein are covered by a cap-rock of andesitic lava, varying according to the topography of the original surface from 80 to 320 metres in thickness. Veta Verde has been proved to have a uniform width of about twelve metres to a depth of approximately 600 metres from the cap-rock. The hanging wall branch veins vary from 70 centimetres to 3 metres in width; they are approximately parallel to each other, and to Veta Verde; the westerly vein (Nueva) has a horizontal distance of about 65 metres from the main vein. In many places in the upper part of the mine the shale is mineralized to such an extent as to constitute ore, and in some instances the silver values in the shale have been higher than those in the siliceous branch veins. To the foot-wall, or east of Veta Verde are other veins, only one of which (Blanca) joins with Veta Verde in depth. The others have a width of from 0·8 to 2 metres. They are irregularly mineralized and are of little industrial importance.

The mineral filling probably resulted from the combined effect of ascending waters through previous existing fractures and by metasomatic replacement of the clastic rocks. The fractures may have been produced by shrinkage of the crustal material, aided by the effect of the intrusives.

The eruptive rocks are mainly andesitic and rhyolitic in dykes and batholiths, which, when they reached the primitive surface, spread out and covered the outcrops with the previously mentioned lava cap-rock. In the lowest working diabasic rocks have been found. The payable mineralization ceases very abruptly, and at a notably uniform level, which is slightly lower than the point where the branch veins split from the main vein, or about 500 ft. below the cap-rock.

PROPERTY OF THE COMPANY.—The company owns eight patented mining claims, having an area of 429 hectares, or practically 1,060 acres, situated on the western slope of the Somera mountain. The mine offices, mill, and cyanide plants are in the State of Michoacán, but a portion of the mining property is in the State of Mexico, and adjoins the mining claims of the El Oro Mining and Railway Co., the Esperanza Mining Co., and the Mexico Mines of El Oro.

The main vein (Veta Verde) has an average strike of N. 18 W. and a dip of about 60°

south-westerly, and has been proved for practically 3 kilometres along its strike and in places to 600 metres upon its dip. Moreover, the Dos Estrellas Company holds 60% of the stock in the old Borda Antigua property in the Tlalpujahua district (about 3 kilometres from Estrellas mill), and during the past year they acquired controlling interests in other small silver properties in the same district. As development work has proved Veta Verde to lose its mineralization in depth, the company has been actively engaged in searching for other properties, and they have options upon various properties including the Veta Grande, near the City of Zacatecas, and a copper-gold property at Las Vigas, State of Vera Cruz.

Developments.—Development has been done by six tunnels from 200 to 1,800 metres in length and by five principal shafts from 150 to 450 metres in depth. Additionally there are six interior shafts of from 150 to 300 metres in depth. There are approximately 60 kilometres of levels, of which about 38 kilometres are open at this time.

Ore Reserves.—The calculated ore reserves at December 31 of each year are shown in the following table :—

Year	*Positive* Metric Tons	*Probable* Metric Tons	Mined during year
1916	469,528	337,551	146,317
1917	213,218	84,166	277,876
1918	453,763	367,056	337,420
1919	542,920	461,292	366,440
1920	429,664	399,535	376,019

Production.—The outputs during recent years are given in the next table :—

Year	Treated Dry Metric tons	Total value of Bullion recovered Pesos	Recovered per ton Pesos	Operating costs per ton pesos
1910	425,878	11,185,443·78	26·26	9·9383
1911	479,889	11,178,096·76	23·29	9·9977
1912	507,018	11,237,311·57	22·16	9·1953
1913	521,799	10,309,630·86	19·76	9·2514
1914	141,824	2,632,526·40*	18·56	9·3550
1915	24,542	173,783·38†	7·08	
1916	164,610	2,412,288·31‡	14·65	9·2330
1917	266,658	4,917,540·62	18·44	14·4847
1918	344,859	7,719,084·06	22·38	13·4167
1919	366,820	7,615,798·05	20·76	11·5499
1920	361,878	6,415,669·98	17·73	12·1700

* Four months. † One month experimental work. ‡ Eight months.

On account of political disturbances, milling was suspended from April, 1914, until May, 1916, with the exception of one month during 1915. The total production from the mine from its inception to the end of 1920 was 4,869,878 dry metric tons.

Equipment.—Dos Estrellas has a complete electrically driven mining plant and machinery, including electric haulage, consisting of eight Baldwin Westinghouse locomotives. The milling and cyaniding plant has a daily capacity of 1,250 metric tons, and comprises two Hadfield gyratory crushers, Merrick automatic weigher, automatic sampler, 120 stamps of 1,250 lb., 108 drops per minute, 14 tube-mills 5 ft. by 24 ft., 29 r.p.m., 14 drag classifiers, 9 Dorr thickeners, Butters filters, and Merrill and Crowe vacuum precipitation plant.

The company owns its railway and rolling stock connecting its mine and mill with the El Oro camp, and also owns lumber forests in the States of Mexico and Michoacán.

History.—The Dos Estrellas property is on the western slope of the Somera mountain, whereas the famous San Rafael vein of the El Oro mining camp is on the eastern slope of that mountain, and at a horizontal distance of about 2½ kilometres from the Estrellas creek. This Somera mountain has a vertical height of about 380 metres above the western river, and on the western slope of the mountain the shale is exposed for about 125 metres above the river, the remaining 255 metres consisting of the andesitic lava cap-rock.

In the shale and at a point about 70 metres above the river, some small veins (known as "Jesus del Monte") outcrop and upon these considerable work was done in the way of test pits ; also a shaft was sunk to a depth of about 125 metres and a 220 metre tunnel was driven from the Estrellas creek for the purpose of cutting these veins in depth. This work was carried out by local Mexicans in a spasmodic manner between the years 1890 and 1897. In 1898 the attention of F. J. Fournier (a Frenchman who was at that time working in a small mining camp about 10 miles north-west of El Oro) was called to the abundance of rich float along the western slope of the Somera mountain all the way from the river to the andesite cap-rock, and he reasoned logically that such did not proceed from the narrow and poor veins of "Jesus del Monte," especially as a great deal of float was found higher up the mountain side than the outcrops of these small veins ; neither did the float come from the strong San Rafael vein on the eastern slope of the Somera mountain, the apex of San Rafael vein being about 280 metres lower than the mountain top. Fournier concluded that the vein which from the float came was buried beneath the cap-rock somewhere in the heart of the mountain but on its western slope, and, acting upon this assumption he denounced the whole of the territory available between the western

ravine and the mining claims of the three principal El Oro companies. He enlisted the services of Baltasar Muñoz Lumbier, a well-known Mexican engineer, and also organized a mining company at Mexico City in accordance with the laws of the Republic of Mexico, having as co-directors some of the best known and most successful Mexicans at that time engaged in local mining enterprises. The company was organized in 3,000 shares of 100 pesos each par value, to acquire and work the mining claims held by Fournier, for which he obtained 5,000 pesos in cash and 1,000 free or fully paid shares in the company.

Muñoz Lumbier laid out the main tunnel (now known as the Estrellas tunnel) in the shale and at a point 360 metres below the summit of the Somera mountain and about 125 metres below the cap-rock, and pointed it straight for the main shaft of the Esperanza mining property, some 2,400 metres horizontally distant. This tunnel is at a point about 320 metres south of the previously mentioned 220 metre tunnel driven earlier by the Mexicans. Work was begun on the Estrellas tunnel on December 27, 1899, and at 240 metres the "Jesus del Monte" vein was cut. A limited amount of driving proved it to be of little merit. At 585 metres a vein known as El Salto was cut, but this, too, had little importance. At 660 metres the bonanza vein (Nueva) was cut. This had a width of 2 metres, and it immediately gave shipping ore of phenomenal richness, several carloads averaging 3 kilogrammes of gold and 85 kilogrammes of silver per metric ton. At the 700 metre point the famous Veta Verde was cut, with a width of 20 metres (about 65 ft.), and averaging 25 grammes of gold and 300 grammes of silver per ton. At once Fournier's fortune was made, as well as that of those who retained their shares and accompanied him in his vicissitudes and pertinacity. As the mine was opened up the reserves developed and the surface equipment and mill expanded proportionately. The price of the shares steadily increased, and a few years later, when the price of the original shares reached several thousand pesos, these were subdivided into one hundred shares each having a nominal value of one peso each. Thus, while the capitalization remained at 300,000 pesos, the number of the shares was increased from 3,000 to 300,000. These were placed upon the Paris Bourse during 1907, and rapidly rose in price until reaching the equivalent of 38,000 pesos per share of original stock. For several weeks the price remained around the equivalent of 30,000 pesos per original share. Later on, during 1913, when it was seen that the end of the phenomenal richness was in sight, and dividends fell off considerably from previous years, a change in management was made. From 1900 to 1913 the management was confined to French and Mexican engineers. Under the management from 1913 to date extensive development work in the bottom of the mine had proved the non-persistence of mineralization in depth, and no discoveries or rich ore had been made during the past few years. Nevertheless, by employing modern methods throughout the whole organization, and by re-working the upper part of the mine, very satisfactory working costs are being obtained and the property continues to be operated profitably and to maintain the leading position among the mines in the El Oro district.

Operations During 1920. — The outstanding features of the year 1920 may be summed up as follows: (*a*) the decline in the price of silver from an average of 131 cents (U.S. currency) per ounce troy in January to 64 cents in December; (*b*) the increased difficulties in the labour situation, partly as a result of political conditions during the year, and in part due to the demand for skilled workmen in the oilfields; and (*c*) the management having obtained, by means of options and contracts, various mining properties in the Tlalpujahua and other districts, thereby taking the indicated steps towards prolonging the life and increasing the activities of the company.

Though the wages of the work-people were gradually increased, during the first-half of the year, yet there was such a demand for operatives of all kinds in the oilfields that the men became insistent in their demands, and demanded conditions economically impossible, with the result that at the end of September there was a strike that caused suspension of operations in the mill during practically the whole month of October. Although the management gained its principal points, the shut-down occasioned a higher operating cost and lower tonnage treated than would have resulted otherwise.

The policy of investigating new properties was pursued most actively, and while as a result of the big fall in the price of silver such properties have lost some of their

attractiveness, those which the company is working in the Tlalpujahua district have been acquired by long-time contracts of such a nature as to offset in part the conditions of the silver market.

The operating costs were somewhat higher than during the previous year, such being due to more development work being done, to higher wages being paid to all work-people, and to the higher first cost of the principal supplies for the mine. In spite of these conditions, the operating costs were, as usual, the lowest in the district.

During the year 3,795 metres of exploration work was done upon and in connexion with the various veins, this work being carried out upon each of the main levels between the + 90 and the −140. Although such work did not add very materially to the ore-reserves, in some instances it served to place ore from the probable to the positive class, whereas in other cases such as Veta del Salto, hanging-wall stringers of Veta Verde, and the deposit against the contact, small increases in the reserves were realized.

The ore reserves compare favourably with the reserves at the end of 1919, notwithstanding the marked difference in the price of silver at the end of 1920, as compared with the previous year. The estimates at the end of 1919 were: Positive ore, 542,919 tons, averaging 5·4 grammes of gold and 141 grammes of silver per ton; probable ore, 461,292 tons, averaging 6·4 grammes of gold and 135 grammes of silver per ton; total, 1,004,211 tons, having an average content of 5·85 grammes of gold and 138·2 grammes of silver per ton.

I estimated that at the end of December, 1920, the reserves were as follows: Positive ore, 429,664 tons, averaging 8·6 grammes of gold and 151 grammes of silver per ton; probable ore, 399,535 tons, averaging 7 grammes of gold and 152 grammes of silver per ton; total 829,199 tons, having an average content of 7·83 grammes of gold and 151·4 grammes of silver per ton.

The production for the year 1920 was 361,878 tons of an average grade of 8·9 grammes of gold and 157·5 grammes of silver. By adding this amount to the reserves at the end of 1920, it will be seen that the ore reserves decreased by only 175,000 tons, showing that approximately 187,000 tons of ore was developed during the year. This increase was brought about by actively exploiting the old stopes upon Veta Verde at various places, but principally between faults from the zero level to the + 36 level, where, in addition to finding payable fills, we frequently found small pillars of high-grade ore. To a lesser extent we are developing similar conditions on the + 72 level, north of Cyamel tunnel, and on the + 90 level towards the south end of the mine. The extent of these payable fills is unknown; hence the difficulty in estimating the tonnage they will produce, but there can be no doubt as to the importance they have upon the future of the mine. I believe that the estimates herewith given are most conservative, and that as we continue exploiting the upper part of the mine we shall continue to find payable ore in places at present inaccessible.

The following table gives an estimate of the ore reserves at December 31, 1920:—

	Positive			Probable		
		Grammes per ton			Grammes per ton	
	Tonnage	Au.	Ag.	Tonnage	Au.	Ag.
Veins:						
"A"	—	—	—	—	—	-

Veta Verde		—	—	13,000	7·26	109·1
Salto	—	—	—	5,000	8·80	109·0
Mineral against Contact ...	—	—	—	2,000	8·00	62·0
Totals ...	429,664	8·59	150·8	399,535	7·00	152·0

The amount of ore treated during the year was 361,877 dry metric tons, having an average content of 8·9 grammes gold and 157·5 grammes silver. The mine produced 373,293 tons, the difference between the ore produced and the ore treated being 11,415 tons, which was added to the stock-pile at El Cedro.

The amount of bullion exported manifests an extraction of 89·2% of the gold and 70·4% of the silver contents. There was produced 1,395 bars, having a calculated value at the mine of 6,415,670 pesos.

The average price obtained for our silver throughout the year was 1·006 dollars, U.S. currency, per ounce troy, compared with 1·121 dollars during the year 1919.

Reference has already been made to some of the factors that increased our operating costs, and to these must be added that of the strike during the month of October, whereby although we treated only a small amount of ore in the mill, yet we endeavoured to keep the mine and some other departments at

work, thereby increasing the general cost of operations.

The operating costs averaged 12·17 pesos per dry metric ton during 1920, compared with 11·55 pesos during 1919. The details of such costs are herewith given, also a comparison with previous years.

	1918	1919	1920
[illegible]	[illegible]	[illegible]	[illegible]
[illegible]	[illegible]	[illegible]	4·46
[illegible]	1·23	1·29	1·21
[illegible]	2·13	[illegible]	1·81
[illegible]	[illegible]	1·17	[illegible]
[illegible]	2·15	[illegible]	[illegible]
[illegible]	0·61	[illegible]	0·51
Totals	13·41	11·54	12·17

During the year we treated in the La Lucha mill approximately 29,200 dry metric tons of ore from the Borda Antigua property, having an average grade of 5·06 grammes gold and 290 grammes silver. The recovery as per bullion exported amounted to 94·5% of the gold and 88·8% of the silver values. During the first half of the year the operations resulted in a small profit being made, but as the price of silver became lower and wages higher, it became unprofitable to continue milling operations; consequently, during the early days of December we ceased all exploitation work and cancelled the agreement between the Borda Antigua and the La Lucha companies, covering the operation of the La Lucha mill. It is the intention to treat Borda Antigua ores at the El Cedro mill when the ore in the mining properties in the Tlalpujahua district is exploited.

In the Tlalpujahua district, the company has several properties under option; these comprise Concepción de Borda, Planeta, San Rafael, and Noche Buena. On the first-named property we accomplished a considerable amount of preliminary work in the way of repairing the main shaft and roadways, unwatering the mine, and installing the necessary machinery to render the mine accessible and to carry on future development work. The results of investigations in the upper or exploited part of the mine indicate the existence of practically 10,000 tons of fills and pillars, averaging about 200 grammes silver and 1·5 grammes gold, while in the lower, or that part of the mine known as the Bonanza winze, there exists as virgin vein matter probably 5,000 tons of ore of about 300 grammes silver and 2 grammes gold. The most interesting and promising point for investigation in this property is north of the big fault, where the vein is intact, and from the second level a working is being driven to intersect the vein at this point, and at the same time to explore the ground between Concepción de Borda and the Planeta properties. The latter property has an interesting record as having produced high-grade silver ore, and we have been re-timbering the shaft and placing a hoist and head-gear in position, and will soon begin the unwatering of this property. Such upper workings as we have rendered assessible show the vein to be completely worked out.

The Noche Buena property is a small one south of the Carmen de Virgenes property. The upper part of the vein has been worked out for its gold as well as silver values, and a long tunnel that was being driven to cut the vein in depth at the time of our acquiring this property did not succeed in finding the vein, owing to it being faulted; in consequence we have been cleaning out the old workings with the view of following the vein downward by means of winzes.

We cross-cutted the entire width of the San Rafael Comanja properties toward their northern extremity, but such work did not result in our finding anything of economic importance; however, the central and southern parts of these properties remain to be explored from the Concepción and Planeta properties.

The task of cleaning out the old working of the Zomelahuacan copper property, near the town of Las Vigas, State of Vera Cruz, has been practically completed, and although the information at present available is far from being complete or final, yet the results of several hundreds of samples from various workings show that the deposits in places carry sufficient copper and gold, so as to render the exploitation of such economically possible with copper at about 15 cents. On the other hand, we now know that the mineralization does not occur in the form of a fissure vein as has previously been supposed, but rather as a contact deposit, and there is little or no continuity between the various deposits exposed which hitherto has been considered as being the case instead of isolated deposits, as we have proved them to be.

A most promising prospect containing gold values examined during the year is the El Tigre in the State of Nayarit, but unfortunately, although it was decided to enter into negotiations to acquire such property under option, legal difficulties have been experienced in the matter of obtaining a clear title to the property and have prevented its acquisition.

THE REAL VALUE OF GOLD

By S. J. SPEAK, A.R.S.M., M.Inst.M.M.

Obviously where gold is the unit of currency its value in terms of money is constant, though its real value is its value in relationship to other commodities. The true value of any commodity is equal to the energy and sacrifice required to produce it, but its market value is subject to the varying effects of supply and demand. Gold differs from all other commodities except silver, in that the demand for it is almost entirely for money purposes, so that should it ever lose its place as the basis of currency the demand for it would be almost negligible, and its market value would be subject to the usual effects of supply and demand, which would result in the closing of nearly all gold mines.

Bankers are generally agreed that some basis unit for currency is essential, and that the most suitable one is gold. Its supposed suitability depends entirely on its past history, which has been that its production has not been subject to violent fluctuations. The discovery of a large and fabulously rich goldfield would destroy its value as a basis of currency.

Gold, therefore, is unlike most other commodities in that the demand for it is mainly of an artificial character. In this respect its position compares unfavourably with that, say, of diamonds, for possesion of the latter is desired for their beauty, whereas few would hold gold on that account.

Even bankers desire to hold as little gold as possible, for without power to issue notes against the gold that they may have in their vaults, they can secure no interest upon it, and gold is therefore held by them only as an emergency precaution. Their aim is to hold as little of it as possible, in accordance with their own ideas of safety.

Thus gold is in the paradoxical position that the demand for it is of an artificial character, and no one in ordinary times wishes to hold it as a commodity.

The indifference displayed by our bankers to the dwindling gold output of the Empire shows that they regard gold mainly as an international token, and overlook the fact that gold takes much labour to produce, and that such labour has not since the war been as relatively well paid as labour in other industries. Of course, there is to be remembered the fact that a year's production of gold is only a small proportion of the world's stock of gold, and bankers may properly regard a temporary deficiency of new output as of small consequence ; yet, on the other hand, currency has been considerably increased during the war, and deflation will have to be exceedingly drastic if the world's currency can ever have the same gold backing as before the war. The declared policy of our own nation, which is no doubt dictated by the bankers, is towards that end. The paper pound is, if possible, to be made equivalent to the old gold pound.

To achieve this end strong efforts are being made to reduce the price of other commodities. The attempt with coal has resulted in a strike which has cost a loss of national wealth of probably over £200,000,000. This was a real loss, which can never be regained, because it was labour being idle instead of productive. The only gain is in the direction of improving the value of our paper currency. Deflation is obviously going to be a very expensive process, and the patient may be killed by it instead of cured.

An alternative method is to recognize the existing inflation, and thereby avoid wage reductions, which we know our workmen will stupidly resist. In comparison with American currency, ours is inflated about 30%, and it is recognized that American currency is also inflated, possibly 50%. America, as a creditor nation, having secured thereby large stocks of gold, will be able to deflate and probably at a much more rapid rate than we, and it may be expected that our exchange with America will go further against us.

Under these circumstances, if our country now recognized an inflation of 50% and adopted a free gold basis on such ratio, the immediate results would be somewhat as follows :—

(1) Wages need be little disturbed for some time.

(2) The Bank of England could purchase gold for internal requirements.

(3) American exchange would fall to near 3·24.

(4) Gold producers would receive nominally more English currency for their output.

(5) Interest payments on internal national debt would be greatly relieved. This

would not be equivalent to capital confiscation if, say, all loans, debentures, etc., raised before 1915 were allowed an increase of 50%, because most of the money raised since that date was in inflated currency. Capitalists would suffer little damage, for they would benefit by the consequent reduced taxation.

(6) All present possessors of cash or bank deposits would suffer possibly to the extent of 15%, which, anyway, is more equitable than that they should benefit to the extent of about 50% at the expense of the rest of the nation, which is what the present deflation policy aims to do.

Unfortunately such a scheme would probably hit bankers more particularly than anybody else, and it is therefore to their supposed interest to avoid it. When, however, we witness the serious trade difficulties and unemployment, and compute what national loss that means, it would probably pay all capitalists in the end to take a possible loss now, a loss more apparent than real.

For the sake of brevity, no argument is offered to show the justice of a 50% premium on gold. Your readers, however, know the general conditions of mining throughout the world, and are aware how poorly the gold miners have been paid for their work as compared with the coal miners of England. Of course, this has arisen from the effects of supply and demand.

What is now suggested amounts to legalizing a 50% premium on gold with the object of avoiding the present painful and wasteful process of currency deflation. In such way we would more quickly attain a settled basis of currency, whereas the existing deflation process must take considerable time, and may never succeed, and, in the meantime, will be a constant embarrassment to trade.

The gold output of the world has fallen about 30% since the commencement of the war, and may fall further unless the principal nations return to a free gold basis at an early date. If Great Britain will require, as has been estimated, ten years to complete its present deflation policy, by that time gold will be relatively scarce, and it will be difficult to acquire sufficient gold backing for its currency. This aspect of the question appears to be overlooked by most financial experts, and the main object of this article is to draw attention to the fact that the matter of gold production has an important bearing on the currency question. The world is an expanding community, and unless gold output keeps pace, currency deflation will have to go beyond the pre-war basis. As the British Empire is now contributing about 70% of the world's output, it is of particular interest to us to support that industry. During the war its product was commandeered at pre-war prices, a treatment served out to no other industry, and since then and is now suffering from lack of normal demand. Meanwhile, America is securing a stock of gold at a price below the fair cost of its production. The danger of the present system if continued is that when we do want gold we shall be required to pay dearly for it, whereas a bold stroke as above advocated would establish a stable currency which would enable the trade and commerce of the country to revive rapidly.

BOOK REVIEWS

A Textbook of Practical Hydraulics. By Professor JAMES PARK. Second edition. Cloth, octavo, 310 pages, illustrated. Price 21s. net. London: Charles Griffin & Co., Ltd.

That a second edition of this work should have been called for within five years after the appearance of the first is ample and satisfactory evidence that it has met the requirements of those for whom it was intended, and Professor Park is to be congratulated upon having so successfully accomplished the task that he had set himself to perform. There is but little in the present edition that calls for comment, beyond the statement that many of the deficiencies that had been noted in the first edition have now been made good. The author has, quite rightly, not departed in the least from his original scheme, although he has somewhat strengthened the theoretical portions which were decidedly weak in the former edition, as was pointed out in the MAGAZINE at the time. It may fairly be hoped that in this respect the author has found the review of his first edition not unhelpful in his work of revision. For example, in the present volume Bernoulli's theorem is stated and is applied to elucidate the theory of the Venturi meter, and in the same way the diaphragm method of measuring the flow of water in a pipe has

been, at any rate, referred to. The account of the Pitot tubes in the present volume is a decided improvement upon its predecessor ; it is, however, not quite accurate to say that when the mouth of the tube points down-stream the water in the vertical limb is depressed by the same amount as that to which it is elevated when the mouth faces up-stream. The depression is, in fact, always less than the corresponding elevation. The treatment of most of the sections is, however, quite adequate and the explanations are clearly put. To an English reader, it appears strange that in a book of this class the author should find it necessary to work out so many of his examples first by arithmetical methods and then again by logarithms. There may be a good reason for this not apparent to us in this country, but here we should have expected that a student capable of reading a work on hydraulics would at least know sufficient elementary mathematics to be able to make a simple logarithmic calculation.

HENRY LOUIS.

Petrographic Methods and Calculations. By ARTHUR HOLMES, D.Sc. Cloth, octavo, 511 pages, with diagrams and illustrations. Price 31s. 6d. net. London : Thomas Murby & Co.

Many books on petrography contain little beyond the description of the megascopic and microscopic characters of the rocks and the methods employed in their determination, but Dr. Holmes has set out to produce a treatise giving a full treatment of the petrographic methods to be employed in the laboratory and at the desk. Much of the matter appears in a British textbook for the first time.

One is struck from the first with the stimulating character of the volume. No chance of indicating a new line of inquiry is missed, and the student who can work through the book without attempting to settle some petrographic problem for himself will be very lacking in imagination.

The chapter on the determination of the specific gravity of minerals and rocks is particularly complete, and includes a description of methods for the determination of the porosity of rocks and of the specific gravity of rocks and minerals at high temperatures ; molecular volumes, isomorphism, and polymorphism are also dealt with.

The separation of minerals is discussed from every point of view except that of flotation, which seems to have been neglected by most petrographers, but in the reviewer's experience forms a useful method in some cases.

The chapters on the optical examination of minerals, sediments, crushed rocks, and thin sections are excellent, and include a most useful chapter on microchemical methods. The textures of igneous and metamorphic rocks are then described in considerable detail, and the book closes with two chapters on the interpretation and graphical representation of chemical analyses of rocks. Useful tables are given in two appendices, and a third consists of a series of excellently reproduced photo-micrographs illustrating rock textures.

Numerous illustrative examples of the methods described are quoted from actual researches and the close connexion between methods of the research-worker and those suitable for use as commercial tests of material is pointed out.

References are given throughout the book to original papers on the various methods described and on researches in which they were employed; this greatly adds to the value of the book.

The book is well illustrated by a series of figures and diagrams, the latter being particularly numerous, the print is clear, and the matter well set out.

Dr. Holmes is to be congratulated on having produced a book which should materially advance the study and practice of petrology.

E. H. DAVISON.

Chromium Ore. By W. G. RUMBOLD. Paper covers, octavo, 60 pages. Price 3s. 6d. net. London : John Murray and the Imperial Institute.

This monograph is one of a series published by the Imperial Institute describing mineral resources, with special reference to the British Empire, and it deals with the same matter as a brochure, one of a similar range, issued last year by the Imperial Mineral Resources Bureau. It is unfortunate that these two Government Departments should publish monographs dealing with like subjects, and some working arrangement between the Institute and the Bureau, to eliminate this overlapping, is desirable.

In Chapter I of the monograph, the occurrences, character, and uses of chromium ore are discussed, and attention is called to

the great increase in production during the war. For some years previous to 1914 the price of the mineral was low, and the principal producers were New Caledonia and Rhodesia, the output being controlled by a joint selling agency. With the greater demand for munitions of war, the deposits of the United States and Canada were intensively developed, and the output from the Indian deposits was also largely increased. Following the cessation of hostilities, prices fell heavily, and pre-war values are now being approached, as well as the standard of quality raised.

Chromium ores are considered to be derived from primary segregations of a peridotite magma, and are generally associated with serpentine rocks, in which they occur as irregular shaped bodies or disseminated grains. By reason of the wide distribution of serpentine, an ample supply of the ores is assured, which will meet the increased demand when conditions are more normal, for the importance of chromium has been greatly enhanced as a result of the war.

Statistics of the output of chromite for the years 1912–19 are given, but would have been improved if they had been accompanied by the value per ton of the mineral c.i.f. British ports over the same period.

The mining and concentration of chromite are briefly described, and it is pointed out that a more general adoption of modern methods would enable producers to reduce their operating costs to meet present-day conditions, as, without doubt, where mechanical concentration is not in operation, a large proportion of the mineral is rejected as waste.

The information given regarding the utilization of chromium is useful. In the production of ferro-chrome alloys in the electric furnace, the carbon contents are high, which is prejudicial when used with low-carbon steels. Subsequent refining will reduce the carbon, but a carbon-free alloy can be made by the "thermit" process of reduction by aluminium.

The virtues of the so-called "rustless steel" have been overstated, as Sir Robert Hadfield pointed out some years ago, but there is a widening field of usefulness for the alloy. As a result of improved heat treatment and variation in composition of the alloy, it is now possible to manufacture cutlery from it with an edge equal to the best high-carbon steel.

Reference is made to the use of chrome ore as a refractory material, for it constitutes an almost ideal lining for furnaces, as, although somewhat difficult to sinter, it has a very high fusing point and is equally suitable for basic or acid working. The use of chromium salts in the dyeing industry is mentioned, but it is probable the largest consumption of chromates in the future will be as a primary coating for iron and steel, which, when covered with a wet-resisting finishing paint formed of oxide of iron and linseed oil is found to be most effective in the prevention of corrosion.

Useful information is given in Chapter II, which describes the principal deposits of chromium ore of the British Empire, and in Chapter III, which deals with foreign sources of supply.

It is pointed out that some of the largest and richest deposits are within the Empire, in Rhodesia, South Africa, India, Canada, and Australasia. Of the foreign deposits, those of New Caledonia, Asia Minor, and Greece are the most important. The production of chromite in the United States reached large figures during the war, but the high cost of concentration will prevent development of the ores in normal times, as obtains with their manganese deposits.

The chromiferous iron ores of Greece and Cuba, which contain 2 to 3% of chromium and 0·5 to 1% of nickel, and which are widely distributed elsewhere, cannot be used successfully for the production of ordinary steel, owing to the extra cost of manufacture due to their refractory character, and the necessity of eliminating the greater part of the chromium in a slag, which is very viscous. A large expenditure has been incurred in developing the Cuban deposits, where the mineral occurs as a mantle, and is excavated by mechanical plant and sintered before shipment. The pig iron produced from this mineral possesses special qualities, by reason of its chromium and nickel contents, and is used as a foundry mixture to increase strength and ductility. In manufacturing steel from it by the "Duplex" process, the greater part of the chromium is oxidized, while most of the nickel is retained, with the result that the finished product contains 1 to 1·5% nickel and 0·25 to 0·75% chromium. This constitutes a nickel-chromium steel, and although of low grade, is, with suitable heat treatment, of greater value than ordinary steel for many purposes.

The bibliography at the conclusion of the monograph should enable anyone interested to obtain more detailed information than is possible to provide in the text.

H. K. SCOTT.

Geology of Mesopotamia and its Borderlands. Compiled by the Geographical Section of the Naval Intelligence Division. Cloth, octavo, 120 pages, with folding maps. Price 5s. net. London: His Majesty's Stationery Office.

Although but recently issued to the public this useful little volume betrays signs of having been written some time previously, for neither in the text nor in the excellent bibliography is there any mention made of the more recent work done in connexion with the geology of these parts, notably of the paper by Busk and Mayo read before the Institution of Petroleum Technologists. One rather obvious defect arising from its anonymous authorship is the difficulty of separating the opinions of the writers and those of their authorities.

In the note which precedes the text we find that "the problems of the economic geology of greatest present interest are those connected with the distribution and correlation of the oil-bearing beds . . ." Some space is devoted to other minerals, but the above forms the keynote of the work, with which all will agree; yet, regarded as a contribution to our knowledge of the oil of these regions, it must be confessed the book has little practical value. Thus, the evident importance attached to the fact that oil seepages have been known historically for 2,400 years (pp. 72 and 84) strikes an oil-man as scarcely justifiable, for the actual period presumably has been far greater, and in any case such considerations are little evidence of commercial supplies being retained. The fact of the development of the Maidān-i-Naftūn pool in Persia is, of course, rather a testimony to the drill than added geological evidence, and its exact significance as regards the field as a whole can be judged only from the detailed geology, which is not touched upon. Again, the evident desire for a "definite estimate of the quantity of oil" before pronouncement as to the prospects of a field shows undue caution and the practical oil-man does not concern himself mainly with the "correlation and number of the promising oil-beds" nor with the expression of opinion of writers personally unacquainted with the area.

Sound judgment formed in the field after detailed plane-table mapping by experienced oil-geologists is the kind of basis required in appraising the potential value of a prospect, and this has to be followed by systematic test drilling co-ordinated with the geological work. The favourable consensus of opinion of oil-men conversant with these regions, which tends to regard them as the principal undeveloped field in the Old World, deserves more weight than is given to it by the authors.

With the above reservations the book may be recommended to all desiring a handy compendium of the general geology of the Persian Gulf and Mesopotamian regions, based mainly upon the works of Loftus, de Morgan, and Pilgrim, with brief reference in Chapter V to Oswald's work in Armenia.

The summary of the geological history in Chapter VII is the most interesting part of the book, both as regards what is already known as well as indicating the important problems yet to be tackled, as, for instance, the southern margin of the Sunkland. The maps and diagrams are carefully made, and the former are not the least useful part of the work.

T. G. MADGWICK.

Handbook of Metllaurgy. Vol. I. By CARL SCHNABEL, translated and revised by HENRY LOUIS. Cloth, octavo, 1,171 pages, with numerous diagrams and illustrations. Third edition. Price 40s. net. London: Macmillan & Co., Ltd.

The first edition of this book was published in 1898, and the second in 1905, and both editions were translations of Schnabel's German editions with brief notices of improvements and new processes made known after the issue of the original work. In the present edition Professor Louis has taken a more original line, for he has adopted the plan of an independent revision, mainly, as he states, on account of the death of Schnabel, and because all the important modern improvements in general metallurgical practice were to be found in English-speaking countries. The war, however, delayed publication of this third edition, much of which had been completed and the type set up by 1914; "therefore," states Professor Louis in the preface, "there are no references to any of the most recent developments in certain departments . . . nor to any of the literature of the last few years." This is almost bound to impair the

usefulness of the book, at least, as far as those are concerned who already possess the earlier edition. The difficulty does not appear to the reviewer as insurmountable, for it might have been overcome by an appendix in which these matters could have been dealt with, and then incorporated in the text of the next edition.

The form of previous editions having been maintained, it will be hardly necessary to say that the present volume deals with the metallurgy of copper, lead, silver, and gold, and that in each case the physical and chemical properties and the reactions of the metal compounds that are of importance in extraction are set forth before the methods of extraction are explained in detail and illustrated by works practice.

The book deals essentially with general metallurgy, that is, with the extraction of the metal from its ores, and the necessary refining operations. Many people, including the reviewer, would have liked to see more reference to the micro-examination of metals in those sections relating to the effects of impurities. For instance, in the case of copper, photo-micrographs of this metal containing cuprous oxide could have been inserted with advantage on p. 3 where reference is made to the eutectic (a metallography term), and, further, the injurious effect of bismuth could have been explained by an illustration of this constituent separating out and forming thin brittle walls between the copper crystals.

Turning now to the methods of extraction and refining, it seems a pity, in view of the fact that an independent revision has been made, that the reviser has not been more drastic in his treatment of processes that are almost obsolete, thereby gaining space for fuller descriptions of the more modern methods and plant. A comparison of the present edition with that published in 1905 shows that the revision has not been as drastic as some would desire. The details of heap-roasting may be important, but surely not of such importance as to require ten pages to be devoted to it, when the description of the Edwards and Merton roasting furnaces is confined to a space of a dozen lines. Another example that might be quoted occurs in the section dealing with the metallurgy of lead. It is stated on p. 565 that "the collection of flue dust is an important element in all lead smelting," and with this statement all lead smelters and refiners will agree. The subject, however, is dismissed in two pages, without even a description of a bag house, the reader being referred for this to the *Transactions* of the American Institute of Mining Engineers, whereas the illustration of the heap-roasting of copper ores is reproduced under lead, a distinct waste of half a page.

It is gratifying to find that the revision of that part of the book dealing with the cyanidation of gold ores is as thorough as could be expected in a volume of this size. Had the other metals been dealt with in a similar manner the book would have been well-nigh perfect.

In conclusion it should be stated that the blame for parts of the new edition being less up-to-date than others must not be placed on Professor Louis, for it is well-known that a reviser of a technical book seldom has the last say, the control of the policy of new editions resting solely with the publishers.

GEORGE PATCHIN.

NEWS LETTERS

PERTH, W.A.

May 22.

TAXATION OF MINES.—During the past three weeks the Royal Commission on Taxation appointed by the Federal Government has been taking evidence in West Australia. The subjects of inquiry covered the equitable distribution of the burdens of taxation, and the giving to primary producers a special consideration as regards the assessment of income tax. A great mass of valuable evidence was collected and proffered on behalf of the Chamber of Mines and the Mining Association, which was most ably placed before the Commission by Mr. J. V. Jukes and Mr. Will Davies, the accountants representing the institutions. Mr. Herbert J. Daly, Mr. H. R. Sleeman, Mr. J. Thompson, M.L.A., and Mr. C. M. Harris gave evidence supplementing the above on behalf of those who are directly interested in finding the capital either in cash or labour to search for and extract gold and the base metal ores. A review of the salient points may be of interest to show to the British investor that some amelioration of the present anomalies in taxation as interpreted may be expected, provided the Federal Government is sincere, and will accept the recommendations of the Royal Commission.

The evidence as it affects the mining industry may be divided into five headings: (*a*) Decrease in the output of gold in Western Australia; (*b*) taxation of sale consideration of mining leases; (*c*) Federal land tax on the unimproved value of a mine; (*d*) the taxing of mines in their early stages; (*e*) the taxation of prospectors.

Dealing with the tax on mining leases, it was pointed out by Mr. Davies that the action of the taxation department in assessing for income tax the sale price of a mine under the guise of such being *payments received by a lessee upon the transfer of a lease to another person* is most unjust. The department admits that the proceeds of the sale of a mine are not taxable as income; nevertheless, it arrives at that very unjust result by taxing the sum received (subject to allowance for capital expenditure on equipment and development, if any) by designating it consideration given on the transfer of a lease. As the Act stands and is administered at present, the prospector who discovers a potential mine, but, being unable to develop it himself, sells it to a company for partly cash and partly shares, or for all shares, may be called upon to pay in taxes on nominal income a greater amount than will be actually realized, this state of affairs being brought about by the taxation of shares at their face value, irrespective of their actual market value, either at the date of the sale of the mine or at the date the return is made by the taxpayer.

In his evidence, Mr. Jukes says on this question that although originally intended to apply to leases of business premises, it is being interpreted in its present form as applying to mining leases, and operates with great harshness. A prospector taking up public land under mining lease may be able to dispose of his interest to good advantage through the discovery of promising deposits on it. Assume he is able to sell for £10,000, he would become liable for £3,421 Federal taxation and the State Act purports to impose £2,300, whereas, if he had won the same amount in a lottery his Federal tax would be £1,400. Of course, if instead of taking a mining lease of land he bought freehold, and then owing to some fortunate circumstance he sold at a profit of £11,000, he would not be liable to taxation on the accretion. From various legal authorities on judgments quoted, it seems impossible to regard a mineral deposit, even though contained in a mining lease, as anything but a fixed capital asset. And even if in the hands of the original discoverer who has paid no fixed sum for the asset, the facts are not affected. He has given time, money, skill, and often suffered great hardships in the search, and the State secures the mineral contents of a certain area of land to him to work, remove, and sell for his own benefit. It is what he retained in the shape of assets upon which he has expended his capital subscribed in the form of his savings, work, and skill.

In the "Kalgoorlie Miner" on October 25, 1919, the Deputy Commissioner of Taxation in dealing with what is the essential value of a lease, thereby meaning buildings, pastoral timber, or gold mining leases states: "My staff valuer would address himself to the gold as a wealth-making factor," and he goes on to say "that is the value of the virgin gold in situ." As Mr. Daly pertinently remarked, the Deputy Commissioner will have to find a superman as a staff valuer, if he is going to appraise the value of gold in situ in a newly discovered mine.

A mining lease differs from all other leases; it is, in fact, a direct licence to deplete a certain area of ground and take from it all its potential and discoverable wealth. The end of a successful mining venture means that numerous deep holes have been made into the earth's crust, and no payable ore is left in the lease. The plant and machinery is usually scrapped or sold for one-tenth part of its original cost. On this point, Mr. Sleeman says: "Sales of mining leases should not be taxed as income, whether sold by individuals or by syndicates or by companies, whether the finders or the promoters. It should be treated as other forms of property in this regard. If this be refused, then as the next best the whole history of the lease should be reviewed. Its purchase price (if any), the money and work spent upon it, the number of years represented by these, and so on. It should, however, be levied only on money when actually received and on actual saleable value of any shares received on payment. Then one could sell some shares to pay the tax on the shares. At present the tax often demands money that a man has not got, and cannot get, or he might be allowed to pay the portion of this tax in shares."

Mr. Thompson cited his own case in which he had sold a mineral lease at Yampi Sound in North-West Australia to the Queensland

Government for £30,000 worth of debentures, and, according to the Federal and State laws, he was liable for £19,000 in taxation. Not only that, but the Federal Taxation Commissioner ruled that the tax must be paid on the face value of the debentures, although he had offered to sell £100 debentures for £85. He was of opinion that as several loans had been floated locally by the Federal Government, and the debenture issues were free from taxation, why not apply the same thing to investors, who put their money into debentures or in developing the country.

Dealing with the question of taxation of unimproved land values in relation to mines, Mr. Davies was in a position to give some very telling evidence in the case of the Whim Well Copper Company. The mine of this company is held partly as freehold and partly leasehold. In the absence of a valuation for the unimproved land tax, which the company, under legal advice, refused to put in, the amount of the tax assessed in default was £4,000, despite the fact that the company had spent over £100,000 more money in developing the mine than they had taken out, and that at the time were not receiving any revenue, as owing to the war they were not able to ship any ore. Considerable argument as to whether the mine came under this Act went on between Mr. Davies for the company and the Taxation Department. Meanwhile, there was a somewhat similar case proceeding in the High Court, based on the value of artesian water below the surface, and eventually the judgment on the case was in favour of the Department. The Whim Well company had to accept this decision, as they were not in a position to fight an expensive case in the High Court. By this time the company had become bankrupt. A few London enthusiasts agreed to find some more money for the mine, but would not do so while what they considered an unjust taxation debt was hanging over the property. Mr. Sleeman, representing the shareholders who were finding this new capital, decided to go to Melbourne and fight the matter out with the Commissioner. He asked whether it was the policy of Australia to encourage mining or to kill it, and whether it was better for the Commonwealth to get £1,988 by way of taxation, or that a big mine should be producing possibly a quarter of a million pounds worth of ore in two or three years, and pay a very large portion of it out in wages? The Chief Commissioner dealt with the matter, and he annulled the whole of the assessment.

The conclusion is that, while as a matter of policy Federal land tax may be of advantage to the community by deterring the locking up of land in large estates, there is neither necessity nor reason for applying such principles to the small areas contained in metalliferous mines, no matter how rich (in isolated cases) those areas may be.

The effect of taxation on new mines was dealt with by Mr. Daly, who contends that income tax was designed as a tax on yearly earnings, on the profits of a company or individual. It certainly was never meant to be a tax on new wealth, the discovery by a prospector or by an exploration company, nor was it intended that the working capital provided to open up new mines should be subject to income tax before any profit had been earned from the gold won from the mine. This statement is given in general terms, and aims at illustrating how the mining industry has suffered a severe setback since legislation provided for tax on transfer of leases and income tax on prospectors consideration. The effects of recent Australian mining legislation have practically blocked the road to raising any new capital in London. The taxation on prospecting operations is one of the chief hindrances to new mining ventures in Australia. A few days ago Mr. Daly received the following instructions from an important London company: "We have, after careful consideration, reluctantly decided not to embark on any gold mining business in West Australia at the present time." Both the State and Federal Acts deal as harshly with mining companies as with the individual prospector.

The case of Charles Bartlow was cited by Mr. Davies. He had been prospecting for over twenty years, with but little success. Some years ago he found a small patch which yielded him some three or four thousand pounds. He put this money on fixed deposit and has been subsisting on the interest while he continued his calling as a prospector. In 1919 his income from prospecting was £40, for the next four years it was *nil*. In November, 1919, he found a rich patch at Lake Austin, which produced £7,754 worth of gold. Deducting the cost for mining and treatment, amounting to £411, his income from personal exertion was thus £7,343. His income from property, that is to

say, the interest he drew on his former find was set at £112, or total taxable income of £7,455. Out of the modest yield of his earlier nest-egg (£112) he is taxed £35 1s. as income tax from property. The tax on income from personal exertion amounts to £1,616 0s. 11d., or a total Federal tax of £1,651 2s. 9d. In addition, his State taxation was £1,647 17s., making his total tax for this year £3,298 19s. Thus he has to pay nearly half of his income. If he had realized the harshness of such an unjust tax, he would not have crushed all the ore in May and June but would have waited to June and July to bring the operations into two different taxation years. Thus he would have saved £2,000.

The Governments have realized the value of the prospector, and have spent large sums of money to foster the industry; men have been trained as metallurgists, geologists, mining engineers, etc., and their experience is an asset to Australia. But if the enterprise and grit of the man who finds the gold or base metals is strangled by unjust taxation, then the whole fabric of mining must fall.

C. M. Harris.

TORONTO

July 6.

Porcupine.—While most branches of mining industry are quiet, there is much activity in the gold camps since labour became more plentiful, and the operations of the current year will probably establish a new high record of production. Porcupine has had such an influx of labour that many have been unable to obtain house accommodation, and are living in tents. The increased efficiency of labour is indicated by the statement that the Hollinger Consolidated is now mining and milling $2\frac{1}{4}$ tons of ore daily for each man employed, whereas when efficiency was at its lowest point it was treating only $1\frac{1}{3}$ tons per day for each worker. At the annual meeting of the Dome Mines Co., on June 14, General Manager H. P. de Pencier stated that since the issue of the annual report there had been a distinct improvement in the outlook and the output had greatly exceeded their expectations. The ore recovered between the 8th and 10th levels had fully carried out the promise of the diamond-drilling, an ore-shoot 360 ft. in length having been developed on the 10th level, while diamond-drilling for 300 ft. below that level indicated even richer ore than had so far been recovered. The McIntyre closed a highly prosperous year on June 30, and a forecast of the annual report places the profits in the neighbourhood of $1,000,000, the grade of the ore reserves having been well maintained at an average of about $11 to the ton. No. 7 vein has been reached by a cross-cut at the 1,375 ft. level, where it shows a width of 20 ft. of ore, stated to carry $30 to the ton. The Allied Porcupine, capitalized at $5,000,000, has taken over fifteen mining claims, aggregating 720 acres, together with the mining plant and mill on the Three Nations property, and has begun active development with satisfactory results. New operations under way include the development of the Big Dyke and the Triplex, formerly known as the Tommy Burns.

Kirkland Lake.—This district is attracting much new capital, interest in it having been stimulated by the prospect of the construction of the proposed narrow-gauge railway. The Lake Shore during May recovered gold to the amount of $29,637 from the treatment of 1,863 tons. A rich ore-shoot is being opened up on the 600 ft. level. The proposed enlargement of the mill has been indefinitely postponed. The annual report of the Kirkland Lake for the year ending May 31 shows a profit on operations of $34,990, compared with $24,499 for the preceding year. The production was $277,007, as against $107,071. A new vein found by diamond-drilling from the 900 ft. level, has been tapped by cross-cutting, and shows gold content of $21 to the ton over a width of 7 ft. At the Bidgood a drift at the 300 ft. level has encountered good commercial ore showing visible gold. Work is in progress at the Goodfish property, about 3 miles north of the producing area, with promising results. The Wood-Kirkland has a force of men engaged in surface exploration. A mining plant will be installed. New enterprises in this field include the Lebel Lode, Ltd., capitalized at $2,000,000, which has taken up 100 acres lying north of the Lebel Oro, and the White Kirkland with $500,000 capital and a favourably located property of 130 acres. The Kirkland Lake Proprietary, which is controlled in London, appears to be about to resume active operations. Mr. S. C. Thomson, of New York, has been visiting the properties, but his report has not yet been published here.

Cobalt.—The silver-mining industry con-

tinues much depressed owing to the low price of silver. The exchange rate between Canada and the United States enables the leading producing mines to continue operations at a low rate of profit. The Nipissing, during the five months ended May, produced silver valued at $721,431, as compared with $1,731,464 during the corresponding period of 1920. The Mining Corporation of Canada is operating at capacity and storing its silver. The alterations in the mill increasing its capacity from 160 tons per day to 300 tons, with improved methods of treatment, have reduced operating costs sufficiently to enable the company to keep working in the expectation of a profit. Recent discoveries on the Buffalo property have increased the ore reserves. At the annual meeting on June 29, President J. P. Watson stated that the most important step taken during the year was the acquisition of a majority interest in the Flin Flon copper property in Manitoba, containing 16,000,000 tons of assured ore and additional possible and probable ore of 9,000,000 tons. The annual report of the Beaver Consolidated for the year ended February 26 shows an operating loss of $3,617, as compared with an operating profit of $158,215 for the previous year. The production of silver amounted to 157,274 oz., compared with 301,781. The mine, which was closed down in December, is kept pumped out ready for the resumption of operations when conditions improve.

SUDBURY.—The British America Nickel Corporation has carried through its scheme of financial reorganization, arranging for capital as follows: $6,000,000 first income bonds; $18,500,000 second bonds; and $20,000,000 common stock. Hon. Edgar N. Rhodes, of Amherst, N.S., speaker of the Canadian House of Commons, has been elected president and managing director, and Captain D. Vogt, president of the Norwegian Nickel Works, who was in charge of the company's affairs during the re-financing period, becomes vice-president and managing director for the European office. The corporation is awaiting an improvement in market conditions before reopening its mine and plants.

GOWGANDA.—At the Castle property of the Trethewey much of the surface equipment has been destroyed by fire, and the mine has been closed down. Re-financing is in contemplation before resuming operations, which will not be a matter of difficulty, as the company has 400,000 shares in the treasury.

VANCOUVER, B.C.

July 7.

MACKENZIE RIVER OIL.—The Imperial Oil Company's monoplane has made its first trip to Fort Norman oilfield. The machine started from Edmonton at the beginning of June, and made the trip in slightly over 12 hours flying time. Stops were made at Smith, Hay River, and Simpson, the water route being followed. Mr. Fullerton, the pilot of the machine, returned to Peace River by power-boat, the return trip occupying 25 days, and the round trip, including the stop at Fort Norman, less than a month. Pontoons have been added to the company's monoplanes, so that they may alight on water. This has diminished their carrying power considerably. Four new oil-boring rigs have been dispatched to Norman by the water route, so this year five holes will be bored, besides the one at Great Slave Lake. It is expected that a number of other concerns will have oil rigs in the field before the summer is over, some of which probably will be in operation.

G. P. Mackenzie, Gold Commissioner for the Yukon, has been appointed a land commissioner for the North-West Territories, in order that prospectors going to and from the Fort Norman oilfield by way of the Yukon may file their claims at Dawson, instead of having to make a special trip to Edmonton, as in the past. There are many that believe that the Yukon route is the logical route to the oilfields both in winter and summer. Steamers ply between Skagway and the Pacific coast ports throughout the year, and there is a year-round train service from Skagway to Whitehorse, over the White Pass railway. There is a passable road from Whitehorse to the new silver camp, at Mayo, and Mayo is only 350 miles from Norman.

YUKON SILVER MINES.—The Yukon Gold Co. took out more than 3,000 tons of high-grade silver-lead ore from its property at Keno Hill during the winter. The laws governing mining in the Yukon and the North-West Territories demand that ore mined in these places shall be smelted in Canada. Owing to the low metal prices at present obtaining, no smelter in Canada was willing to purchase this ore, so, by an Order in Council permission has been granted to have it smelted in the United States, and the ore is being shipped to the Selby smelter, at the head of San Francisco bay.

British Columbia Output.—The annual report of the Minister of Mines for the year 1920 has just been issued. It shows the value of the mineral production for the year to have been $35,543,084. This figure is within $50,000 of the preliminary estimate, issued early in January, though the individual items that go to make up that total are vastly different from the early estimate. As I stated at the time the preliminary estimate was issued, the output of zinc then given was far too great; the revised figures now show the estimate to have been nearly 30 million pounds in excess of the actual production. The lead output given at that time, however, was some 18 million pounds, and the copper output two million pounds too low; consequently the total value of the final estimate has come out pretty close to the preliminary one. The preliminary estimate is made before all the returns have been received, and evidently this year some of the lead output was credited as zinc. As both metals come from the same mines, the error is an understandable one.

The following table gives the mineral production for 1920, those of the preceding year being given also, for comparison:—

	1919.	1920.
Gold placer oz.	14,325	11,080
,, lode ..oz.	152,426	120,048
Silver .....oz.	3,403,119	3,337,849
Copper ....lb.	42,459,339	44,887,676
Lead ......lb.	29,475,968	39,331,218
Zinc ....lb.	56,737,651	47,208,268
Coal long tons	2,267,541	2,595,125
Coke long tons	91,138	67,792

The output of gold was 32,378 oz. less than during the previous year. This was to be expected, as the price of labour and supplies remained high throughout the year, causing the Nickel Plate mine at Hedley, one of the principal producers, to close in September. For the same reason little placer mining was done in the province. The Rossland mines, too, were closed on account of labour troubles for a considerable part of the year, and had it not been for the energetic work at the Surf Inlet mine and the opening of the new Premier mine, the gold production would have been much lower than it was. With the general reduction in the wage-scale, amounting on an average to a reduction of $1·25 per man per day, there has been a revival in both placer and lode-gold mining, and at the present time everything points to a much larger production of gold this year.

But for the production from the Dolly Varden and Premier mines the output of silver would have been much less than it was, as the Slocan district, which is the principal silver-producing district of the province, was closed by strikes during the early part of the year and by the depressed condition of the lead and zinc market towards the end, the silver from this district being obtained as a by-product in the production of lead and zinc. The consequence was that the output of the Slocan was less than half of what it was in 1919.

The output of copper was maintained through the energetic operations of the Granby company throughout the year, and of the Britannia company for the first ten months of the year. Too much praise cannot be given to the Granby company, which in the early part of the year was in a really precarious condition. A change of management in June, 1920, however, has pulled the company out of the fire. A gradual decrease in the cost of the production of copper from 18·38 cents per pound in the first half of the year to 14·01 cents for the second half was effected. This has been still further reduced this year, and at the present time copper is being produced at 12·44 cents. There is still, of course, no margin for profit at the present price of copper, but it is expected that still further reductions will be made in the cost of operation, and, now that the coal strike in Britain has been settled, there is likely to be an improvement in the price of the metal.

The increase in the lead production is due almost entirely to the output from the Consolidated Mining and Smelting Co.'s Sullivan mine at Kimberley. This is turning out to be a really remarkable mine, and last year accounted for about 26 million pounds of lead and 42 million pounds of zinc, together with more than 300,000 oz. of silver. The production of the Slocan, which used to be the lead and zinc district of the province, produced only 6 million pounds of lead and less than 4 million pounds of zinc. The reason for the low production has already been given under silver.

The slight increase in the production of coal has all come from the Crow's Nest district, where the seams are large and more cheaply worked. The output per underground employee was 797 tons, and for all employees 535 tons per man. The corresponding figures at the Vancouver Island collieries were 591 and 385 tons respectively. With these outputs per man it is difficult to understand why the retail

cost of coal remains so high. In the Crow's Nest field 101,649 tons of coal was converted into coke in behive ovens, and 67,792 tons of coke was produced. At the Granby company's by-product ovens, at Anyox, 106,969 tons of Vancouver Island coal blended with 15,755 tons of Alberta coal produced 75,690 tons of coke, 884,394 gallons of tar, 296,125 cu. ft. of gas, 151,862 gallons refined motor fuel, and 2,466,355 lb. of ammonium sulphate. [This coke does not appear to be included in the returns in the table.—EDITOR.]

The only other minerals worthy of consideration were 600 tons of manganese ore, running better than 50%, which was produced from a new discovery on Cowichan Lake, Vancouver Island, and 7,500 tons of fluor-spar, valued at $175,000, which came from Rock Candy mine, in the Grand Forks division.

Considering the depressed condition of the base metal market during the latter part of the year, the report cannot be considered as other than satisfactory. It is difficult to make any predictions for the future at this time. The Granby is practically the only copper concern operating in the province at the present time, and it will not account for more than 30 to 35 million pounds during this year. The Britannia cannot possibly get its new mill finished this year, and, considering that the Canada Copper Corporation shut down with copper at 15 cents, it is hardly likely that it will restart this year. The Consolidated Mining and Smelting Co. will produce a small amount of copper as a by-product from its Rossland gold-copper ores. It is keeping up its lead and zinc output, more than 200,000 tons of ore having been delivered at the smelter during the first half of the present year, against 383,000 for the whole of last year. It has improved its electrolytic zinc process, too, considerably, and is obtaining a much better extraction. The Premier Gold Mining Co. will have its concentrating plant and new tramway finished, and should give a much larger output than ever before. An enormous ore reserve has been developed at the Premier, and the mine may be confidently trusted to give a continually increasing output of silver and gold for some time to come. The Belmont-Surf Inlet Mines, Ltd., is opening up a new mine, about three-quarters of a mile from the present one, and it, too, should give a good account of itself. The Dolly Varden mine, which provided more than a quarter of the silver production last year, has not been reopened this year. The tenor of the ore runs about 37 oz. of silver per ton, and, with the heavy cost of maintenance of the mountain railway from the mine to tide-water, this figure gives little margin for profit at the present price of silver. The president of the company paid a visit to England with a view to obtaining capital for a concentration and cyanide plant at the mine, but the time of his visit, with the coal strike on hand and consequent waning rate in money exchange between the two places, evidently was not propitious. A considerable sum of money has to be paid off to the old company before the title of the mine is clear, and this would make it difficult to raise capital. Given a concentration plant, indications point to the Dolly Varden becoming a good property. Unfortunately, however, development work has not been maintained, and this would add considerably to the difficulty in getting money.

Mining is still very quiet in the Slocan, for the double reason that the prices of silver, lead, and zinc remain low and there is no satisfactory outlet for the product, the Consolidated Mining & Smelting Co. being able to obtain all the lead and zinc ore it requires from its Sullivan mine, and the tenor of the bulk of the ore in the Slocan renders shipping to United States smelters unprofitable, on account of the high freight rates.

NEW BOOK CATALOGUE

The Technical Bookshop of THE MINING MAGAZINE has issued a new catalogue of books relating to mining, metallurgy, geology, and kindred subjects, including oil and petroleum. This catalogue will be sent post free on application.

PERSONAL

F. O'D. BOURKE has left for Nigeria.

L. MAURICE COCKERELL left on August 3 for New York and Mexico.

JOSEPH CRANKSHAW has gone to Peru to take over the management of the New Chuquitambo gold mines.

HARVEY DODD is expected from Brazil.

B. E. FRAYLING has returned from Nigeria.

O. T. GORTON is home from Portugal.

F. R. HOCKEY, superintendent of the iron mines of the Broken Hill Proprietary, has arrived in London by way of the United States, and is now visiting the Swedish iron mines.

HENRY C. JENKINS is visiting Roumania.

FRED JOHNSON has been awarded the degree of D.Sc. by the Birmingham University.

T. J. JONES has returned from the United States.

V. F. STANLEY LOW is expected home from Sweden shortly.

D. J. MACDONALD has left for West Africa.

WILLIAM MCNEILL is back from Mexico.

PERCY MARMION has been appointed general manager in Burma for the Burma Corporation.

HUMPHREY M. MORGANS has returned from the East.

ARTHUR E. PAGE has left for the mines of the Ashanti Goldfields Corporation, West Africa.

G. ROOSE PATON has left for Nigeria.

H. G. PAYNE has left for Rhodesia.

JOHN POPE has gone to South Africa.

ALBERT REIS is back from Spain.

H. F. G. ROOSE is back from Colombia.

T. SKEWES SAUNDERS has resigned as manager of Las Dos Estrellas, El Oro, and has opened an office as consulting mining engineer at 525 Edificio La Mutua, Mexico City.

F. F. SHARPLESS has been appointed secretary of the American Institute of Mining and Metallurgical Engineers. He will be remembered in this country as American representative of the Consolidated Mines Selection Company. As to his personal character it may be said that he does credit to his Quaker parentage.

R. G. STICKLAND is expected shortly from Sarawak.

S. C. THOMSON has been appointed consulting engineer to the Kirkland Lake Proprietary Company.

J. B. TYRRELL has been elected chairman of the engineering section of the American Association for the Advancement of Science, which will hold its next meeting at Toronto in December.

ARTHUR L. WALKER, professor of metallurgy in the Columbia University, is on holiday in Europe.

A. T. WATSON has gone to the Gold Coast for the Goldfields of Eastern Akkim

P. B. WAUGH is now resident in Hungary.

A. HOWELL WILLIAMS has returned from Chile.

ERNEST WILLIAMS is back from Canada.

CHARLES H. EDEN, vice-chairman and managing-director of Vivian & Sons, Ltd., Swansea, died on July 28.

WILLIAM CROSLEY died on July 31. He was for many years in the service of Edmund Davis, and was well known in West Africa as manager of the Abbontiakoon and Prestea Block A.

CORNWALLIS F. H. SMITH, for nearly 50 years on the City reporting staff of *The Times*, died last month. He was well known in many circles where his wide knowledge and accuracy of style were fully appreciated. As a reporter of company meetings he was unexcelled, Mr. Chisholm, of the *Mining World*, being his only rival.

TRADE PARAGRAPHS

The works of the METROPOLITAN-VICKERS ELECTRICAL CO., LTD., at Trafford Park, Manchester, were described and illustrated in the *Iron and Coal Trades Review* for July 15.

HYATT, LTD., of 4 Thurloe Place, South Kensington, London, S.W. 7, send us their latest sectional catalogue showing the application of their roller bearings to elevating and conveying machinery.

The WOLF SAFETY LAMP CO. (WM. MAURICE, LTD.), of the Star Works, Leeds, send us particulars of their acetylene lamps; and the FEDERATION LAMP CO. (WM. MAURICE, PROPRIETOR), send us a pamphlet relating to their new electric miners' lamp.

DANIEL ADAMSON & CO., LTD., of Dukinfield, near Manchester, send us a pamphlet giving a brief account of the expansion of their business since its foundation in 1851, and of some of their specialities: steam-engines, turbo-blowers, air-compressors, etc.

A. J. M. SHARPE, at one time with the Broken Hill Associated Smelters, and more recently managing director of H. S. Willcocks & Co., Ltd., has established the INTERNATIONAL METAL SERVICE, with offices at 13–14, Walbrook, London, E.C. 4. The object of this service is to supply commercial and technical information relating to mines, ores, metals, chemical products, etc.

THE SULLIVAN MACHINERY CO., of Chicago (London Office: Salisbury House, E.C. 2), send us Bulletin 78*a*, which describes their dry vacuum pumps of single-cylinder type. These are equipped with the Sullivan improved wafer-type plate valve for both intake and discharge openings. They are built for steam or belt driving. All the moving parts are enclosed and are fully lubricated by the splash method.

METAL MARKETS

COPPER.—The standard copper market in London at the beginning of July exhibited quite a firm tone, but later on values receded. The chief feature in the situation has undoubtedly been the appreciation of the dollar, which tended to restrict demand from Europe, and by curtailing the United States' export sales caused weakness in the New York quotation, and a sympathetic easiness here. As regards the London market, there is little doubt that the firm manner in which values held up during the coal stoppage discounted the improvement in consumption which was expected to follow the settlement, and although some slight improvement has been noticeable of late, it has not been sufficient to sustain values, which have been ruling at below the American parity. America, of course, is and must continue to be, the dominating influence, and much will depend on the attitude of producers there. The latter recently have shown rather more willingness to shade prices, and it may be that they have at last realized that the only way to restore the industry to a firm basis will be to cut down costs and reduce prices. The present United States output is, of course, drastically restricted, and only the vastness of the stocks in existence there and the paucity of world demand prevent its effect being felt at the present time. With regard to European demand, both France and Germany are taking fair quantities; and in this connexion it is rather surprising that Germany should be the chief foreign purchaser of American electrolytic at the moment, bearing in mind that she has to pay in cash owing to the fact that the credit scheme of the Copper Export Association has not been applied to her. Reports from Huelva are to the effect that the copper mining industry there is in a not too hopeful condition, but, in response to an appeal from the management the workmen have volunteered to work extra time without pay. A report from Australia states that there is no possibility of immediate resumption of smelting at the Hampden Cloncurry, unless a substantial reduction in wages, freights, and stores is effected.

TIN.—A drifting tendency has been noticeable in the London standard tin market during the past month, and after a slight rally at the commencement values steadily receded. Consumption during July was consistently poor, chiefly owing to the non-appearance of the expected revival in the tinplate industry. With genuine consumers practically out of the market, the standard market was inevitably dominated by the tactics of professional operators who are apparently unwilling to give the market much support. At one time a little inquiry was seen from the United States, no doubt inspired by the proposal to impose a duty of 2 cents per lb. on imported tin, but on the whole American demand has been quiet, neither the fall here nor the drop in sterling exchange succeeding in attracting any serious buying interest. The Continent, however, has been a moderate purchaser of late. As regards the East the belief that production there is somewhat in excess of current demand seems to be confirmed by the greater willingness to sell, which is now apparent in the Straits. Fair quantities, indeed, have been disposed of there at comparatively reasonable prices. The future of the market is a little obscure at the present time, as, although the quotation may not necessarily be exorbitant, the existence of large, tied-up stocks in the East and the probability of a further surplus accumulating cannot be regarded with much optimism.

Average price of cash standard tin: July, 1921, £164 13s. 1d.; June, 1921, £167 12s. 10d.; July, 1920, £262 1s. 5d.; June, 1920, £250 18s. 6d.

LEAD.—Remarkable steadiness was the feature of the lead market in London during the month of July, and values on balance were little changed. A fair amount of speculative activity of a bullish nature was evident, but this factor alone hardly accounted for the firm appearance of the market. Holders have continued their firm attitude, while consumers have also maintained their previous policy of buying mainly for immediate delivery. The net result has been that not only has the concentration of consumers' demand upon the prompt position been a sustaining factor, but that whenever delayed shipments entailed a shortage of near metal, values rose appreciably. Under these circumstances, the early position still commands a fair premium over forward. Consuming demand, on the whole, has been much better in this market than in most of the other metal markets. Indications are not lacking that possibly the near future will see larger arrivals of lead, and it is quite probable that Spain will cease to feature as the sole supplier. Indeed, during July metal arrived here both from Australia and America, and should Mexico continue to dispatch fair quantities of metal into the United States, further shipments from the latter country are to be expected. As regards Australia, it is not believed that Broken Hill consignments on any scale are possible for some time yet. In America the market has been easy on the whole, and some interests have withdrawn owing to the fact that the present prices mean a considerable loss. Quite possibly further cuts will be made in the United States output.

Average price of soft pig lead: July, 1921, £23 5s. 10d; June, 1921, £22 9s. 1d.; July, 1920, £35 9s.; June, 1920, £35 1s. 4d.

SPELTER.—The course of values in the London spelter market during July was steadily downwards, although the net loss was not considerable. This seems to have been due to the continuance of an extremely poor consuming demand and rather more willingness on the part of holders to liquidate. Probably some holders have got tired, which is not surprising in view of the present poor industrial outlook and the complexity of the spelter situation. The expected revival in the galvanizing industry has not yet materialized to any extent, and, indeed, seems impossible just at present, and therefore very little improvement can be expected in genuine consumptive demand. On the other hand, supplies have continued restricted. The Silesian question is still undecided, and what with the Reparations Act and the German-Polish dispute, fresh supplies are unlikely from that quarter for some time. Belgium and Norway have recently displayed a

little more desire to sell and moderate quantities have come in. The stocks in the United Kingdom are not particularly extensive, but are quite ample to meet the poor demand which at present exists. Production in Belgium is still restricted and was some 4,370 tons in June, against 4,360 tons in May. In the United States the market has been dull, and the position there does not inspire much confidence. At the moment, however, conditions are hardly favourable for shipments of surplus metal from that country to this side.

Average price of spelter: July, 1921, £26 12s.; June, 1921, £27 2s. 2d.; July, 1920, £42 13s. 3d.; June, 1920, £42 2s. 11d.

ZINC DUST.—Prices are fairly steady; high-grade Australian £55 per ton, English 92 to 94% about £52 10s., and American 92 to 94% £52 10s.

ANTIMONY.—English regulus has kept very steady; ordinary brands £37 to £40, special brands £38 5s. to £42, and 98 to 99% £29 to £32. Foreign in warehouse shows a slight advance on the month at £24 10s. to £25 per ton.

ARSENIC.—The market has continued dull, and the quotation for Cornish white is nominal at £45 per ton, delivered London or Liverpool.

BISMUTH.—No recent change has been made in the quotation, which continues at 7s. 6d. per lb.

CADMIUM.—The price continues at 6s. to 6s. 3d. per lb.

ALUMINIUM.—The quotation is about £115 to £125 per ton.

NICKEL.—Producers quote £190 for both home and export, but this price is somewhat nominal.

COBALT METAL.—The price is nominally 15s. to 16s per lb., but there are sellers at slightly less.

COBALT OXIDE.—Black oxide is still quoted at 12s., and grey is also unchanged at 13s. 6d. per lb.

PLATINUM AND PALLADIUM.—Platinum is unchanged, manufactured material being priced at £20 and raw at £17 per oz., while palladium is also steady, with manufactured metal quoted at £20 and raw at £15.

QUICKSILVER.—The market is quiet, and values are slightly lower at about £10 17s. 6d. per bottle.

SELENIUM.—Sellers quote 10s. 6d. to 13s. per lb.

TELLURIUM.—The quotation is easier at 80s. to 90s. per lb.

SULPHATE OF COPPER.—The quotation is unchanged at £30 per ton, for both home and export.

MANGANESE ORE.—The price of Indian grades is rather nominal at 1s. 2d. per unit c.i.f. U.K.

TUNGSTEN ORE.—The market is quiet and variable. The present quotation for 65% WO_3 is about 12s. 6d. to 13s. 6d. per unit.

MOLYBDENITE.—The quotation is dull and rather nominal at 42s. to 50s. per unit c.i.f.

CHROME ORES.—Indian and African grades have eased slightly to £4 10s. c i.f.

SILVER.—The London silver quotation was firmer during the month of July. The price opened at 35¼d. on the 1st, rose to 37½d. on the 9th, relapsed to 36¾d. on the 11th, advanced to 37¾d. on the 13th, and then fell to 37d. on the 20th. Subsequently the quotation was marked up to 39½d. on the 28th, followed by 38¾d. on the 29th. The price closed the month on July 30 at 39½d.

GRAPHITE.—Madagascar, 80 to 90%, has kept very steady at £20 to £25 per ton c.i.f.

IRON AND STEEL.—The resumption of operations on the part of producing plants, since the settlement of the coal dispute, has been slow. This is mainly accounted for by the price of coal, which is still too high to permit of economic working. A very few blast-furnaces have been started, and the product of most of these is for use in the same plants. Most ironmasters are reluctant to resume production till they see a chance of doing so at a profit, and a substantial reduction in coke prices will be necessary if the prices of home producers are to be on a competitive basis with Continental offers. The stocks of good grades of foundry iron in makers' hands are very low, as a result of the protracted stoppage of production In the case of manufactured material the delay in starting is no doubt partly attributable to lack of sufficient orders to permit of regular working. There is a certain amount of inquiry about, but business is slow to mature. Keen competition is still in evidence on the part of the Continent, and a fair amount of Continental material is changing hands.

THE MINING DIGEST

A RECORD OF PROGRESS IN MINING, METALLURGY, AND GEOLOGY

In this section we give abstracts of important articles and papers appearing in technical journals and proceedings of societies, together with brief records of other articles and papers; also notices of new books and pamphlets, lists of patents on mining and metallurgical subjects, and abstracts of the yearly reports of mining companies.

GEOLOGY OF PACHUCA AND EL ORO

At the February meeting of the American Institute of Mining and Metallurgical Engineers, Horace V. Winchell presented a paper giving some of his impressions of the geology of the Pachuca silver district, and the El Oro gold district, Mexico, obtained during a visit a year ago. His hints as to future work are of considerable practical value, and will be of interest to shareholders in the various companies at El Oro and in the Santa Gertrudis.

Pachuca.—Pachuca district is believed to have been discovered in 1522, and its present output is nearly one-sixth of the silver production of the world. The district consists of a series of mountains and valleys, the minor features of which extend in an easterly and westerly direction and reach elevations of 8,000 to 10,000 ft. above the sea. The range as a whole constitutes a continental divide; its axis runs northerly and southerly and separates the waters that flow westerly into the Pacific Ocean from those flowing easterly into the Gulf of Mexico. On the north and east the surface falls rapidly to the warmer zone, and is cut by deep canyons. In this warm country about 4,000 ft. below the summit is a canyon 2,500 or 3,000 ft. deeper that drains the region on the eastern slopes. Dense forests, heavy undergrowth, and much soil cover the land. On the western slope there is a different atmosphere and country; the vegetation is relatively sparse and the conditions semi-arid. The rocks are either bare or covered with laterite; they are often weathered and rotted to a considerable depth. According to the best weather data obtainable, there is a marked difference in the amount of rainfall on the two slopes, within the few miles occupied by the operating mines, on the north and east the rainfall being far greater than on the west. These conditions suggest a difference in the chemical activity of surface waters, which seem to have played an important part in the genesis of these extensive ore concentrations.

Tertiary eruptives similar to those that contain so many of the mines of Mexico and the south-western part of the United States are conspicuous features of the geology. The underlying basement on which these volcanoes were deposited is probably Cretaceous sediments, but none was observed in the area covered by these notes. The oldest rock seen is the older andesite. This is a thick flow of inconstant texture, and varies from a massive rock with few phenocrysts to a highly porphyritic mass in which are many whitened felspars and some altered pyroxenes with occasional biotites. Toward the north and west this typical andesite is succeeded by a quartz andesite, or dacite, much more siliceous, lighter in colour and with many quartz phenocrysts ranging in size from $\frac{1}{32}$ to $\frac{1}{8}$ in. in diameter. Whether the dacite is a phase of the older andesite or a separate flow was not ascertained. No definite line of contact was seen. Both of these rocks contain fragments of darker fine-grained andesite, and both at times exhibit marked flow structure. They can hardly have been intrusives, for there is no remnant of any covering rock. Moreover, at times the vesicular or amygdaloidal texture characteristic of rocks cooled near the surface is found.

The older andesite appears on the surface over the greater portion of the area thus far developed by mining operations. It can be traced continuously from a point more than 1 mile east of the Guerrero mill of the Real del Monte Co. to a point west of the Bordo shaft, where it passes beneath later eruptives, about 12 miles. Its width on the surface is much less, since its northern margin is south of the northern limit of underground mining operations, and may be seen just north of the valley in which are situated the Paraiso and Santo Tomas shafts. Its southern limit of exposure was not traced. Within this older andesite are east-west zones of extensive and profound thermal alteration in which the rocks have been altered over areas probably several miles long and often hundreds of feet wide. The altered rock is softer and lighter in colour than the fresh andesite, and carries occasional pyrite crystals, with calcite films and veinlets, and even quartz incrustations. It is in these altered zones in the older andesite (and dacite) that the important ore deposits have been found and developed.

The succeeding rock is later andesite. This consists of flows, breccias, and tuffs, all highly porphyritic and generally less massive than the older andesite. It is, however, sometimes thick-bedded and dense and so similar in appearance as to be distinguished with difficulty except on weathered surfaces. It weathers in various colours from reddish brown to bluish or purplish grey and covers large areas north of the actively mined district. In places, only a thin shell of this rock is left; elsewhere shafts go down through it into the lower andesite. In the Girault tunnel, the contact is well exposed; near the Trompillo shaft there is a steep fault contact between the two formations with the Vizcaina vein lying between. This later andesite has not been considered promising ground for exploration, and has produced but little ore. Whether this prejudice is based on its actual poverty or not is a question that can be answered only by future and deeper development, where this later formation attains great thickness. So far as the author could learn, the only workings in it are comparatively shallow (at least in the central portion of the district), and do not attain depths where, even in the older andesite, valuable ore-bodies are first encountered.

Still younger, and overlying the later andesite, is rhyolite. This rock is cream coloured and occurs on the surface in thin flows and tuffs, often much weathered and cut by small arroyos. Rhyolite or quartz-porphyry dykes of the same material are also seen on the surface and underground throughout the district from the Santa Gertrudis north to

the Capula and from the crest of the main divide above Real del Monte west to and beyond the Bordo. These dykes have various strikes and dips, but the large and more continuous ones strike and dip parallel to the main productive vein systems. On the surface and underground these rhyolite flows and quartz-porphyry dykes are cut by the vein fissures, which are sometimes particularly well mineralized and contain large stopes where they abut against or rest upon the dykes. At Capula the vein, carrying ore in two or more strands, is in a quartz-porphyry dyke of great longitudinal extent and from 50 to 100 ft. thick, dipping southerly about 50°.

Cutting later andesite, but of undetermined age relation to the rhyolite is basalt. This rock is seen in east-west dykes from 5 to 40 ft. thick, and a general northerly dip in the country west of the Pachuca mineralized area. It is not much weathered. It stands up in bold outcrops, and is dense and tough and contains abundant olivine phenocrysts. The later andesite near these dykes has been weathered and oxidized, and the red belts have sometimes been mistaken for veins.

So far as could be observed, all the veins of the Pachuca district belong to the same general period of fracturing. Although some veins terminate against or are faulted by others, the evidence tends to show that all of the productive veins thus far developed were formed and primarily mineralized at one period, and from the same agencies and structural disturbances. Nevertheless, there are two systems of veins; one striking east and west, and one striking north and south. The east-west veins are said to have been first discovered and worked, although the north-south veins, which are rich and wonderfully productive, have also been worked for many years. The latter occur in the eastern part of the district, largely in the property of the Real del Monte Co. Most of the east-west veins have numerous branches extending both north-easterly and north-westerly, forming what has been termed "linked vein" structure, quite typical of rock fracturing on a large scale. Some of the branches extend throughout the intervening space between the stronger east-west veins; others apparently die out before reaching any great distance. The full extent of the north-south vein system has not yet been disclosed, nor is it known how many such veins remain to be discovered. They seem to terminate on the south against the great Vizcaina fissure, although the Dios te Guie is said to be displaced by the Vizcaina and to extend a short distance south of it, without, however, containing much ore.

The principal veins of the east-west system are the Santa Gertrudis, Fresnillo, Anàlcos, Vizcaina, Maravillas, Santa Ana, and Polo Norte. La Corteza and El Lobo veins strike north-westerly, while the Veta del Tajo, Cristobal Colon, and Florencia strike to the north-east.

So far as developed, the north-south veins, in their order from west to east, are the Dios te Guie, San Sabas, Purisima, Santa Ines, Santa Brigida, and Veta de la Reina. The stoping width of these veins varies from 3 to 40 ft., and some of the ore-shoots, such as that in the Purisima (N-S) vein, are 400 metres long. The large east-west veins contain some of the longest ore-shoots ever developed, reaching 1,000 metres in the Santa Gertrudis vein and as much in the Vizcaina. The horizontal dimensions of the ore-shoots generally exceed the dip-length. The bearing of this fact on the question of ore genesis will be suggested later. The dip of the east-west veins is generally to the south, at angles of from 65° to 80°. Local north dips are not uncommon. The north-south veins dip both easterly and westerly; it is said that the former are the more productive.

The veins occupy planes of fracture and zones of shearing and are composed of crushed country rock more or less completely replaced by quartz and other vein minerals. The best veins, from the standpoint of productivity, are in and course through the zones of greatest rock alteration, and yet there was occasionally observed a belt or barrier of fresher looking rock just before coming to a vein. Such a belt lies just east of the east-dipping, north-south Purisima vein.

There are evidences of two generations of quartz deposition. The first period quartz, which replaced the broken andesite and often presents a banded or curved structure suggestive of its deposition around rock fragments, is white and bony or ivory-like. Upon and around this white quartz and in its interstices is a darker later quartz carrying silver minerals with pyrite and a little galena and, still rarer, crystals of blende and chalcopyrite. Where not replaced by quartz, the vein filling is sericitic or kaolinic. The quartz is usually broken into fragments, especially where the veins are wide, but is sometimes solid and "frozen" to the hard country rock. Some veins have good walls; some are in "bad ground", some are accompanied by well-defined planes of movement on one or both walls or in the veins themselves. The best and most abundant ore seems to be in those veins that are quite open to the passage of ground water. There is not a great flow of water, considering the length of underground development. As the rainfall at Pachuca is so much less than that at Real del Monte, it is probable the eastern mines make more water than those in the western camp.

It is a singular and significant fact that on the western slope oxidation extends to the lowest productive levels, about 2,000 ft. from the surface. This is not intended to imply that no sulphide minerals remain. The sulphide of silver, argentite, is the principal ore-mineral, and pyrite is quite abundant; but the quartz is honeycombed, rhodonite and rhodochrosite are more or less altered to psilomelane and pyrolusite, horn silver is apparent, and calcite coatings are found on the joints and in cavities. The effect of weathering is naturally greater as one approaches the surface, and, indeed, not only the silver but the quartz itself seems to have been dissolved out of the upper portion of the veins and carried downwards. It is only occasionally that quartz and ore persist upwards to the grass roots. Few stopes extend high enough to make their presence known by surface settling, and the average prospector acquainted with the camp states without hesitation that good ore can hardly be expected short of 400 or 500 ft. in depth. This has a familiar sound, but seems to have more than an element of truth here. Long ore-shoots, already fully explored and mined upwards to their terminations sometimes have tongues projecting to the daylight; but the average line of the upper margin of the long shoots is perhaps 150 metres from the surface. Indeed, there seems to be a general parallelism between the surface topography and the configuration of the ore-shoots below. This rule may possibly not hold where there is a con-

siderable thickness of recent volcanics, even though such rocks are cut by the vein fissures. It must be admitted that there is no rule without exceptions and that no general statement is applicable to every vein in the district. There are stopes that reach the surface ; there are ore-shoots that do not persist downwards ; there are veins whose production has come from within 500 ft. of the present surface and others that are chiefly barren to that depth and productive below it. Nevertheless, there is a remarkably persistent general relation between the surface and the upper limit of the pay ore. This relation becomes still more striking when the termination of the ore downwards is considered. There seems to be little doubt in the minds of those familiar with Pachuca that the mineralization has a rather abrupt and very definite termination in several fully explored mines, and that the productive area of the veins is confined within a vertical range of about 2,000 ft. Moreover, in no one ore-shoot is the full extent of this zone mineralized. The average height of the pay-ore zone is, perhaps, 1,500 ft., in many cases less, and in a few cases more. It is a matter of common knowledge that the veins scatter, the quartz diminishes, the values fall off rapidly, and only occasionally are found any sulphide or base minerals such as blende and galena. This general situation is not in any way exceptional for veins in Tertiary eruptives, but the explanation may not always be the same nor the geological record so easily read.

In considering the possibilities of a mining district an understanding of its geology and something as to the probable genesis of its ores is valuable as a guide in explorations and in appraising its future. The facts given may be summarized as follows: (1) The country rock is a series of Tertiary volcanics. (2) The vein fissures cut the entire series from the oldest to the youngest. (3) parallel to the veins are quartz-porphyry dykes of considerable extent. These are not universally known, but are in sufficiently constant association with the veins to be taken into consideration as possible agents in ore genesis. (4) The country rock is not only widely sheared and fissured, but presents evidence of profound alteration by thermal waters over wide zones. (5) The country rock is still further altered by weathering from the surface down to considerable depth. (6) The veins are largely quartz, but this quartz seldom comes to the surface and never in such quantity as in the veins underground. This statement is true of veins and their outcrops, whether found on the crests of mountains or in deep valleys. In other words, both quartz and ore lie for the most part some distance below the surface. (7) Oxidation and leaching persist to the lowest levels of silver enrichment. Horn silver, native silver, and argentite (the last greatly predominating) are the ore minerals. They occur in white quartz, which is itself secondary, or as incrustations or cavity fillings, together with pyrite and an occasional speck of chalcopyrite and galena. For the most part oxides of iron and manganese are present, though in diminishing amount as depth is gained. (8) There are seldom any massive sulphide ore-bodies in the veins beneath the oxidized ore, nor are there in the upper levels the large masses of oxidized material that often indicate the former presence of heavy sulphide bodies. (9) The major axes of the ore-shoots are more nearly horizontal than vertical ; so much so that the Pachuca district is almost unique in this respect. (10) The vein quartz dies out downwards, and even large veins dwindle into a series of scattered and unmineralized stringers. (11) All the mineralized veins belong to one general period and contain the same kind of ore. The products of the district are silver and gold in the ratio of about 5 gm. of gold to 1 kg. of silver.

With reference now to the richly productive portion of the Pachuca camp, the history of ore formation may well have been somewhat as follows : Having accumulated in large mass, the andesites, both older and later, slowly cooled, and zones of shearing were produced by shrinkage and subsidence. Through the multitude of cracks and fissures vapours and hot waters penetrated the rock and effected widespread alteration, depositing at the same time barren pyrite in disseminated crystals over zones of considerable width. When these fissures extended to sufficient depth there was another outburst of magma, this time quartz-porphyry and rhyolite, followed by the usual period of hot-spring activity. At this time the first quartz was deposited in and along the fissure already formed and replacing and silicifying the broken andesite along the shear zones. The period of subsidence and fracturing was not yet at an end, for the quartz-porphyry itself, after cooling sufficiently, was fractured and fissured and somewhat mineralized. Then, with the dying down of fumarolic and hot-spring activity, came the opportunity for surface-waters, which up to this time had been operating solely on the exposed surfaces, to begin working their way downward along the fissures and shear zones, oxidizing and dissolving the scattered sulphides and carrying them to new resting places at lower levels. It is not known how much erosion has taken place since these Tertiary rocks were formed, but that it may well have been thousands of feet is shown by the depth of the valleys in the immediate vicinity. On the western slope of the mountains chemical changes are rapid, and with an already altered rock on which to operate the upper parts of the veins were constantly and successively oxidized, leached of quartz, silver minerals, pyrite, and gangue minerals, while the surface was eroded and carried away. Always the values were held in the veins and carried downward in advance of the dissipating forces of erosion, and times without number the little films of argentite that had been deposited at a safe depth and were becoming endangered by the slow approach of the surface, were removed still deeper. In this way there is the cumulative result, first, of ages of primary deposition, during which perhaps no commercial ore-bodies were formed, and, second, of a long period of weathering under a hot sun and climatic conditions distinctly favourable to secondary enrichment. The proof of the theory is in the character of the minerals, the leaching and other evidences of the work of descending waters, as well as the shape of the ore-shoots, their correspondence with the topography of the surface, the paucity of quartz at grass roots, and its diminuendo habit beneath the ore accumulations. In short, all the broad phenomena of the district seem to be in accord with this theory and with no other. It is supported by both the positive proof and the negative facts, by the minerals found as well as by those that are not present ; it is a most excellent example of the formation of large and deep ore-bodies by secondary sulphide enrichment.

Similar forces working on similar materials under similar conditions, for an equal length of time, may be expected to produce similar results. Thus, with equal precipitation and evaporation over the entire district, uniform surface gradients on both sides of the divide, and similar rocks uniformly sheared and fissured so as to offer equal receptivity to drainage, there would probably result a similarity in topography and in the subterranean products of weathering agencies. Where the materials are similar but the conditions are known to vary, it is reasonable to attribute heterogeneity of products to such variance of conditions ; and where the rocks are different, products may be formed by the operation of similar forces under similar conditions. At Pachuca, the rocks are, in general, similar mineralogically and structurally ; the operating forces are similar, although not of equal intensity nor volume ; the time factor is practically constant ; but the products have a wide variance in different portions of the district.

Reference has been made to the marked difference in the annual precipitation on the western and eastern slopes of the continental divide, but its effect has not been fully described. The first result to be noticed is in the different sculpturing of the surface. On the eastern slope the topography is rougher, the slope gradients are steeper, the changes in elevation more frequent and abrupt. On the western slope there are many long, smooth, gently sloping hillsides, and comparatively few sharp and deep canyons. As a consequence, the rainfall, if equal over the two areas, would run off faster on the eastern than on the western slope, and a smaller amount would percolate downward into the rocks. But with the much greater rainfall on the eastern slope, it might be expected that the effect of surface waters would be at least as great, and oxidation as deep in Real del Monte as in Pachuca. In fact, considering alone the much greater precipitation, one would expect deeper and more intense oxidation. But the reverse is the case. Sulphide minerals are rarely found within 300 ft. of the surface in the western part of the camp, while they are abundant within 70 ft. of the surface about 1 mile east of the Guerrero mill, on the eastern side of the range. It is probable, as already stated, that there is more water in the mines and in the ground generally on the eastern than on the western slope. The question arises, why, then, is there such a marked difference in the depth to which oxidation has extended ? No doubt many factors enter into the problem. It is evident at a glance that erosion is more rapid, and that it nearly keeps pace with oxidation, on the eastern slope. But there are other reasons why sulphides in that section are so much nearer the surface. It may be explained in part by the fact that the rain waters are not so active chemically after soaking through the soil. There is perhaps not enough difference in temperature to make any material difference, although such difference probably exists. It is perhaps more largely due to the fact that the rank vegetation that covers the eastern foot hills deprives the rain of its oxygen, and hence the underground waters in that section are comparatively inert. In this respect Pachuca offers a rare example of the effect of differing climatic conditions on the depth and character of mineralization in veins. In another respect, also, it is interesting. Many observers here and in other districts have noted the fact that there is oxidation below the present water table, and have attributed the phenomenon to a change of water-level in comparatively recent time. This does not appear to be the only, nor, indeed, always the more probable, explanation. Where, as is probably the case here, the entire volume of ground water is slowly moving downward, and yet is ever renewed by annual rainfall, there must be oxidizing action until all the oxygen is consumed, and thus even below the surface of the subterranean water-table, extending downwards perhaps several hundred feet, the sulphide minerals will become oxidized.

El Oro.—For his data on El Oro, the writer is indebted not alone to his personal examination, but to a report on the camp by Waldemar Lindgren, written in 1913. From this report are taken the following more general statements, in order to lay the foundation for points that seem to be of special interest to the economic geologist. The district of El Oro is situated on the high plateau of Mexico, near its western edge, at an elevation of about 10,000 ft. On this part of the plateau broad valleys are separated by irregular groups of mountains rising 2,000 to 3,000 ft. above the depressions. The valleys are filled with volcanic tuff and detritus. The mountains are largely built up of volcanic flows, mainly andesite, but at many places the underlying older rocks are exposed. The latter consist of calcareous shales of Cretaceous or Jurassic age, and in places contain an older series of igneous rocks intruded into the shales and exposed by erosion. The geological sequence is then as follows : (1) Calcareous shale with some sandstone and limestone. (2) Older Tertiary igneous rocks intruded into or poured out on these sedimentary shales. (3) Formation of fissure veins intersecting shales and older igneous rocks. (4) Epoch of erosion. (5) Late Tertiary and recent igneous rocks, chiefly flows of lava and tuffs, resting on eroded shales, older igneous rocks and veins, and showing no mineralization. (6) Recent epoch of erosion.

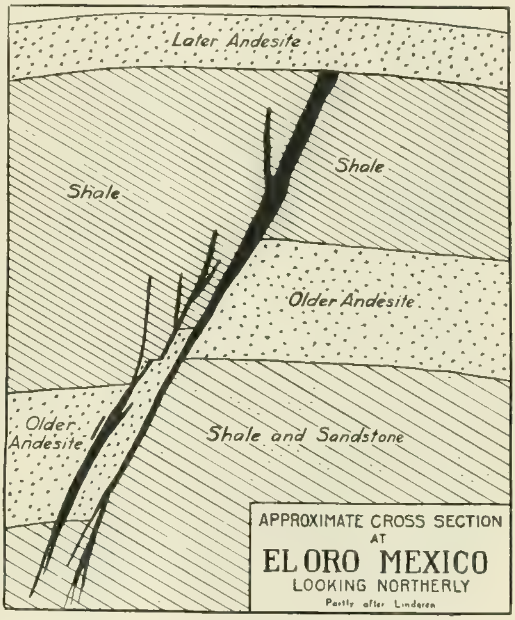
The younger surface lavas are mostly massive, dark-grey, hornblende-andesites, which are oxidized and disintegrated near the surface, but show no mineralization, nor do they contain pyrite. Toward the valley agglomerates and tuffs gradually take the place of the massive rocks. Where the contact with the shales is exposed by mining operations, a few feet of reddish stratified material of fragmental origin often rest directly on the shale. The thickness of this lava is manifestly affected by the recent erosion. Along the San Rafael lode, south of North shaft, it is less than 200 ft., but north of this point it increases to 400 ft., and at Tiro Hondo and San Patricio shafts it is about 600 ft. Under the summit of the hill the thickness is 1,000 ft. Dykes and intrusive necks of this lava are found in the adjoining Esperanza mine.

The older andesite is a greenish dense rock, which has been greatly altered by the vein-forming agencies and now contains much pyrite, calcite, and sericite. It occurs as thick intrusive sheets, or as irregular masses in the black shales, also as smaller dykes. On the property of the El Oro Co. none of this rock reaches the present surface or the old surface underneath the younger andesite, but it forms a thick flat body which is about 600 ft. thick ; it was first encountered in the northern part of the property along the San Rafael vein, about 600 ft. below the capping. Farther south, it lies deeper, being near the interior shaft at about 900 ft. below the capping ; and in the Carmen mine

its top lies again about 800 ft. below that surface. The lower contact with the shales has been found in the northern part of the mine. Throughout, this andesite sheet, or sill, is faulted by the fissure of the San Rafael, the vertical throw being, in the vicinity of the Somera shaft, about 670 ft. Down to about the 1,300 ft. level, the andesite appears only in the foot-wall. Below the 1,300 ft. level, it begins to appear in the hanging wall, and continues to form that wall down to the 1,600 ft. level, the lowest point reached. (Since Lindgren's examination the mine workings have developed ground far beneath the lower margin of this sill.) The older series of andesite is represented both by intrusive rocks and lava flows.

The predominating sedimentary rock is a black, bituminous shale, well stratified and often containing much calcite, in fact, grading into a calcareous shale and occasionally into a black granular limestone. In places the shale contains embedded masses of a dark-grey friable sandstone. This sandstone is more abundant in the deep levels, and is typically present at the station and cross-cut of the Somera shaft on the 1,300 ft. level. When examined in the field, this rock was held to be of tuffaceous origin, but the microscope has shown it to be a pure quartzose sandstone. The sedimentary rocks lie horizontal, or at slight dips that exhibit no marked irregularity. A total thickness of 1,300 ft. of strata is exposed in the workings.

Mr. Winchell proceeds as follows: We have at El Oro a series of veins bearing gold and silver minerals in a quartz-calcite gangue. These veins are fissures that were filled by replacement and infiltration. Some of them are evidently fissures of considerable displacement. They cut through the black shales and through the sill of andesite that was intruded horizontally into these shales, and which, as a natural consequence, is both overlain and underlain by the shale beds. After the veins were formed and mineralized, they were subjected to the action of surface waters for a considerable time, and an unknown extent of their upper portions was removed by erosion. They are oxidized to the depth of nearly 1,000 ft., and their silver content at least was secondarily enriched by the action of descending waters. The general strike of the veins is about N. 30° W., and their dip at varying angles to the west. They have branches in both foot and hanging walls, but more numerously in the latter. After a long period of weathering and erosion the country was covered by more recent lava flows, which were in turn weathered and eroded until in some localities the underlying shales and one vein, the first discovered Descubridora, are exposed on the surface. These lava flows and volcanic tuffs are not penetrated by the veins which cut the underlying rocks. The veins are, in turn, cut and displaced by north-dipping east-west faults. These faults are unmineralized, except by a little calcite, which may be of recent deposition. Their general effect has been to step the country down to the north. The direction of movement along several of these faults has been diagonally downwards to the east. The andesite sill varies in thickness from 400 ft. to possibly more than 700 ft.; it has been cut and displaced by the vein fissures with throws of several hundred feet. The most productive ore-bodies have been found in the veins where they lie within the shale overlying the andesite sill and adjacent to it, where, by reason of faulting movement along the vein fissures, the shale is brought in opposition to the andesite. There is also some ore found where the veins lie wholly in andesite, but not in large quantity anywhere above the lower margin of the lower faulted segment of the sill. Developments indicate that the veins are not enriched for any distance below the andesite. Quartz, indeed, is found to persist for some distance beneath it, but with diminishing tendency downward, and with smaller ore-shoots. The quartz scatters in stringers of diminishing strength, and dies out. The lower stretches of the veins contain some of the baser sulphides, such as blende and galena. The commercial ore-bodies occur in long relatively horizontal ore-shoots better mineralized in the upper levels. Some of these shoots have been definitely bottomed while others are still being pursued through their downward reaching lobes and tails.



APPROXIMATE CROSS SECTION AT EL ORO MEXICO LOOKING NORTHERLY
Partly after Lindgren

It is seldom in the course of geological study that the facts observable suffice to point strongly to a particular mass of eruptive rock as the source of vein mineralization. In this respect El Oro is of particular interest. The position of the ore-bodies in the ground and their relation to the andesite sill, the dwindling of the quartz and mineralization downward suggest that it was the fountain head of ore-deposition. There is nothing to suggest the presence of other sills or masses of intrusive rock, and many facts that lead one to doubt their existence. This holds true of all the veins thus far developed. They are large and rich above the sill and poor and small or entirely pinched out beneath it. This could hardly be the case if they had been formed from solutions rising from greater depth. This theory is useful as a working hypothesis, for it not only suggests the futility of costly exploration beneath the sill, but at once shows the attractiveness of territory overlying the sill still unexplored and now covered by later andesite, which caps the vein-carrying shale.

REMOVAL OF COPPER FROM BASE LEAD BULLION

The *Proceedings* of the Australasian Institute of Mining and Metallurgy, No. 38, 1920, contains a paper by D. C. M'Garner entitled: The Treatment of the Copper Impurity in the Lead Ores Smelted by the Sulphide Corporation, at Cockle Creek, New South Wales. The question of dealing with the small quantities of copper found in a great many of the purchased ores became a factor of importance when the Sulphide Corporation decided to refine its own lead bullion, as the presence of this impurity has a marked effect on the efficiency of the desilverizing operations of the Parkes process.

The copper is removed from the base bullion by drossing, which collects the copper, and at the same time has considerable gold, silver, and lead values. The drossing of the bullion is done in two stages: firstly, at the smelters; and secondly, in the copper kettles at the refinery. In both cases a wet dross is produced, which is subsequently sweated in a suitable type of furnace. When dry the dross is raked out and stored until enough accumulates to warrant a run on dross in the small blast-furnace kept for that purpose. A typical assay of the dry dross is as follows: Au, 0·3 oz. per ton; Ag, 55 oz. per ton; Pb, 60–70%; Cu, 6·5%; Fe, 2·2%; Zn, 1·5%; Sb, 4·5%; As, 1·6%; S, 4·5%. The accumulated dross is treated in a small blast-furnace with the necessary fluxes, producing a low-grade Cu–Pb matte and base lead bullion. The assay-value of the matte is approximately as follows: Au, 0·05 oz. per ton; Ag, 30 oz. per ton; Pb, 23·2%; Cu, 23–25%; Fe, 25%; Zn, 3·0%; Sb, 5·6%; As, 3·3%; S, 14·4%.

This matte was formerly crushed, roasted, leached with H_2SO_4, and copper precipitates produced; but owing to the shortage of scrap iron some other means of converting the copper into a marketable form had to be sought. The conversion to bluestone showed most promise, and with this object in view the low-grade matte is crushed through ¼ in. screen, given a quick roast in the rotary furnaces, then over a Dwight-Lloyd machine, and finally worked up to high-grade matte in a reverberatory furnace. In working the low-grade up to high-grade matte, the time of treatment is gauged by the Fe contents of the charge, and when a dip sample shows the Fe to be about 2% the charge is tapped, irrespective of the copper values. The lead loss is naturally high, but provision is being made to connect the reverberatory furnace to a bag-house in the near future. An average assay of the high-grade matte produced is as follows: Au, 1·125 oz. per ton; Ag, 69 oz. per ton; Pb, 24%; Cu, 47%; Fe, 2%; Zn, 2·4%; S, 17%. The high-grade matte is crushed in a Krupp mill through 40 mesh screen, roasted in a 4-hearth hand reverberatory furnace, and then passed on to the leaching department for the production of bluestone. The temperature aimed at when roasting is between 600° and 625° C, the following tests being taken under working conditions: No. 1 hearth, 460° C; No. 2 hearth, 532° C; No. 3 hearth, 582° C; No. 4 hearth, 618° C. An average sulphur assay of the roasted product is as follows: Total S, 7·7%; S as SO_4, 7·4%.

The copper is dissolved out of the matte by leaching with dilute H_2SO_4 in an ordinary circular agitation vat provided with a wooden paddle, which is driven by a spur and pinion wheel fitted over the top of the vat. Two such agitators are in use, and they are employed for either leaching the roasted matte or purifying the neutral leach liquors. Sometimes one is treating matte and the other is purifying liquors, and at other times they are both purifying accumulated neutral liquors. The production of a neutral impure liquor occupies from 1 to 5 hours, whereas 5 to 15 hours are necessary for purification, according to the quantity of iron present; therefore an accumulation of impure neutral liquor takes place. In making up neutral liquors, the roasted high-grade matte is carefully weighed, then tipped into the agitator, which has been previously filled to the correct level with H_2O (or acid wash liquors from a previous charge) and a calculated quantity of H_2SO_4. Sufficient acid is added to give a neutral liquor containing 70 to 80 grm. per litre of copper. The temperature of the liquor is kept up to about 70° C by means of live steam delivered to the bottom of the agitator. Samples are taken during the agitation, and a test made for Cu, Fe, and free H_2SO_4. When the copper in the solution is correct, and the acid neutralized, the agitation is stopped, the steam turned off, and the pulp allowed to settle, the clear liquor then being syphoned off to the storage vat for impure neutral liquors. It has been found that at least three leaches can be made before it is necessary to discharge any residues. The copper content of the matte, of course, controls the size of the charge to the agitators, and consequently the number of charges treated before discharging a residue.

After the third neutral liquor has been syphoned off, two successive acid washes are given to the residues. Each wash is given about 2 hours' agitation with 5 to 10% H_2SO_4. Live steam is used to raise the temperature to about 60° C. Periodical tests of the wash liquor for copper and acid are taken, and, when no further increase of copper in the solution is shown, the agitation is stopped, the pulp is allowed to settle, and the clear acid-wash liquor is run off to the wash-water storage vat. From the vat it is subsequently pumped back to the agitator for the next charge to make up neutral leach liquors of the required strength. After the second acid wash has been settled and run off, sufficient water is added to flush the whole of the residues out of the agitator through a bottom discharge into No. 1 of three cone-shaped settling vats, which are terraced to flow from No. 1 to No. 2, and so on, finally overflowing into the storage vat for acid-wash liquors. These vats allow the pulp to settle, and the clear wash water, which contains a little copper, is either displaced by running in fresh water to No. 1 or by syphoning off to the acid-wash storage vat. The thickened pulp is discharged through a bottom discharge pipe into a large brick bin, where it is allowed to dry out sufficiently to be sent to the roasting department. All bluestone plant residues, which represent about 40% by weight of the original high-grade matte leached, are incorporated in the Huntington-Heberlein pot charge, which forms part of the ordinary daily charge to the blast-furnace. Of the metal values in the high-grade matte treated, all of the Au, Ag, and Pb is retained in the residues, together with 46% of the Fe, 32% of the Zn, and 9·5% of the Cu. The Au, Ag, and Pb values are thus separated from 90·5% of the copper, and are subsequently recovered with the bullion produced

in the blast-furnace, the copper that escaped solution being again drossed off.

Iron is the chief removable impurity, and during its precipitation the whole of the As and Sb is also precipitated. The Hofmann system of purification has been successfully employed. This system claims that in the presence of air and CuO (in hot liquors) ferric sulphate is oxidized, then precipitated as ferric oxide, and that a chemical equivalent of copper goes into solution as $CuSO_4$. A considerable departure from the somewhat elaborate purifier, as described by Hofmann, has been made, and all liquor purifications are carried out in an ordinary agitation vat. Several methods of applying the air have been tried, but the best results have been obtained by delivering the air and steam at a point near the bottom of the agitator, either by two independent lead pipes of equal length strapped together—one for air and the other for steam—or by mixing the air and steam in one lead pipe. Whichever method is applied, the lead pipe is securely fixed to the inside of the agitator by means of wooden cleats.

The agitator is filled to the correct level with impure neutral leach solution. A sample of the liquor is taken and tested for iron in the ferrous state, the agitator is then started, and steam and air turned on. For the necessary CuO either ordinary roasted high-grade matte or roasted copper precipitates are used, and, as the temperature rises in the agitator, about 300 lb. of roasted matte or precipitates are tipped in. The progress of the purification is carefully watched by means of a sample of the liquor taken every hour, and a test made for ferrous iron by acidifying the sample with H_2SO_4 and titrating direct with standard $KMnO_4$. In the presence of the added CuO (in the roasted matte or precipitates) no appreciable iron in the ferric state is found in the solution; therefore a titration for Fe in the ferrous state gives a true working indication of the total iron in the solution at any stage of the purification. The amount of Fe in the impure neutral liquors varies considerably, according to the iron in the matte treated and the completeness of the roasting. The maximum Fe found in the impure leach liquors is about 10 grammes per litre, and the minimum about 2·0 to 2·5 g.p.l. The degree of purification aimed at is from 0·15 to 0·2 g.p.l. Fe. From 5 to 15 hours' agitation and aeration are necessary, and, when the purification is finished, the agitator is stopped, steam and air turned off, and the charge allowed to settle. The clear solution is then syphoned off to the storage vat for purified liquors. The following tabulation shows the completeness of the removal of Fe, As, and Sb, the Zn not being affected :—

	Cu	Fe	As	Sb	Zn
Impure liquor (g.p.l.)	73	5·1	1·05	trace	3·0
Purified liquor (g.p.l.)	80	0·15	trace	nil	3·1

After decanting the purified liquor, the residue, which contains a considerable bulk of precipitated ferric oxides, is given a weak acid wash to dissolve the unconverted CuO. About three hours' agitation is given. The residue is allowed to settle, and the liquor decanted to the acid-wash liquor storage vat. If necessary two acid washes are given, then the residues are discharged, with water, in exactly the same manner as ordinary leach residues when making up neutral impure liquors. All acid-wash water is used as subsequent leach solutions for fresh charges of impure liquor.

The main evaporating pan is a rectangular lead-lined wooden vat of 750 gallon capacity. The first arrangement consisted of six 4 in. lead-covered boiler tubes let into the vat longitudinally, with a fire-box, suitable for burning coke, at one end, and a chimney at the other. The rate of evaporation proved to be altogether too slow, and the coke consumption was abnormal. Steam coils were then installed, the first being a 1 in. soft-lead piping. The best results have, however, been obtained by using 1½ in. Sb–Pb piping, containing 4% Sb. On account of the strength of the hard-lead piping the scale can be periodically removed without injury to the coil. A percentage analysis of the scale that forms is as follows: Pb, nil; Cu, 28·8; Fe, 0·4; Zn, 0·9; Sb, trace; As, 0·9; total S, 14·5; S as SO_3, 14·5. The evaporator will not hold enough concentrated liquor to fill a crystallizing vat, therefore when the liquor in the evaporator has attained a specific gravity of 1·4 it is run to a storage vat provided with lead coil, using the waste steam from the evaporator. This storage vat acts as a further concentrator, and also as a means for thoroughly clarifying the liquor before its gravitation to the crystallizers, where it is delivered at from 1·42 to 1·43 sp. gr. and from 80° to 85° C.

The crystallizing vats in use are made of brick, lined on the sides with 8 lb. sheet lead, and with 10 lb. lead on the bottoms. The dimensions of the vats are 8 ft. by 10 ft. by 2 ft. 9 in. high, and their capacity 1,370 gallons. To give the maximum of surface for bluestone crystals to build upon, each vat has 112 sheet-lead strips 8 in. wide and 4 ft. 3 in. long, hung on 4 in. by 2 in. hardwood battens, and allowed to extend down into the vat to within about 7 in. of the bottom. When it is desired to fill a crystallizer, all the strips are placed in position; the hot concentrated liquor is gravitated from the storage vat, covered over with hessian, and allowed to cool slowly for from 7 to 9 days. From 2 to 2·5 tons of dried bluestone are made per charge. When the crystallizer is to be emptied, the mother liquor is ejected by means of a steam ejector. The crystals are all knocked off the strips and sides on to the bottom of the vat, then shovelled out and delivered to the washer. Thus two products are obtained from the crystallizing vats: (1) Mother liquor; (2) bluestone crystals.

An average analysis of the mother liquor is as follows in terms of grammes per litre: Cu, 84; Fe, 0·8 to 2·0; Zn, 11; Free H_2SO_4, 1·8; Sp. gr., 1·26. The original procedure was to further concentrate the mother liquor and produce a second crop of bluestone, but it was found that the resulting crystals were of low grade, which necessitated their being dissolved and re-crystallized. The assay-value of the low-grade bluestone thus produced was: Cu, 24·95%; $CuSO_4, 5H_2O$, 97·5%; Fe, 0·065%; Zn, 0·15%.

As only a first-class grade of bluestone is being boxed for sale, the necessity of re-dissolving the low-grade bluestone cut the capacity of the plant down to such an extent that some other means of dealing with this product had to be devised. The present practice, which overcomes the production of any low-grade bluestone, is to by-pass, and run over scrap-iron, a definite quantity of mother liquor each week, returning the balance to the purified-liquor storage vat. By this means no building up of the zinc (which is the chief impurity) takes place, and a high grade of bluestone only is

made. The copper precipitates, produced from the mother liquor, which is by-passed, represent about 15% of the copper leached from the matte. It is roasted, and returned to the purifier as a source of CuO. The only bluestone now being re-dissolved is the undersize from the hutch of the washer. This is dissolved in mother liquor in an agitator provided with a paddle and steam coil. The crystals are added to the liquor until a specific gravity of 1·435 is obtained. The liquor is then run into the crystallizer with ordinary concentrated purified liquors.

The bluestone, as it comes from the crystallizing vats, has to be washed and freed from any very fine crystals. This is done in a jigger washer, having a fixed screen. Mother liquor is used as the wash liquor. The screen on the washer has 3/32 in. holes, which allow the undersized crystals to pass through into the hutch; from there they are periodically shovelled and sent to the re-dissolver. The washed crystals are shovelled off the jigger screen into a centrifugal drier, from which they are transferred, when properly dried, to a screen giving two sizes of crystals less and greater than ¼ in. The boxes used are made of pine, and have an inside dimension of 20 in. by 10 in. by 12 in. Each box is lined with brown paper before being filled, and holds 1 cwt. net of bluestone, of either the coarse or fine grade of crystals, and is branded C or F, according to which grade of crystals it contains. The assay-value of the finished article is as follows: Cu, 25·26%; $CuSO_4$, $5H_2O$, 99·23%; Ni, 0·002%; Zn, 0·09%; MgO, trace; CaO, trace; Al_2O_3 + Fe_2O_3, 0·07%; As, trace; Sb, trace; Se + Te, trace; Nitrates, nil; Insoluble, 0·02%.

It will be noticed that, although about 15% of the copper leached out of the high-grade matte is by-passed and precipitated on scrap-iron, the precipitated copper is roasted and returned to the purifier; therefore, by the method above described, a metal, which is looked upon as an impurity in lead smelting, is separated from the Au, Ag, and Pb, and converted into a profitable by-product.

Gyroscopic Surveying Compass. — In the MAGAZINE for April, 1920, reference was made to the gyroscopic compass, the principle of which lies in the fact that the axis of rotation of a rapidly rotating body tends to assume a position parallel to the axis of rotation of the earth. This type of compass is now being used in ocean-going steamers, and in the notice named we mentioned that the principle was being applied in Germany to mine surveying. Last month the specification of a patent, granted to Anschutz & Co., of Kiel, was published. This was numbered 18,346 of 1920 (146,372). We quote the specification herewith.

On the bed-plate 1, which is provided with foundation-bolts 2, is cast the horse-shoe-shaped bracket 3. The drawing shows only the rear branch of the said bracket; the front one is assumed to be cut off, the cut surface being visible at 4. On the inner sides of the branches of the said bracket 3 are mounted—shown dotted—supporting parts 5 on which a spherical vessel 7 rests, by means of flanges 6. This vessel is filled with mercury and contains a spherical float 8 which supports the gyroscopic compass 9 by means of a bracket 10 which is connected by a neck 11 to the float 8. Into a bore 12 of the neck 11 projects, through a bore 13 of the bracket 10, a centering-pin 14 secured at the top to the bracket 3.

In the gyroscope compass itself, the gyroscope casing 9 is supported by means of pins 15 in bearings 16 of the bracket 10, so that it may be turned about itself. On one side of the bracket 10 is mounted a spring-controlled locking-pin 17, which engages in the position illustrated, with a notch 18 provided in a plate 19, secured to the gyroscope casing 9. Exactly at an angle of 180° relatively to the notch 18 there is provided in the plate 19 a second notch 20, with which the pin 17 can also engage. The gyroscope casing may therefore be brought either into the position shown in the drawing, or into a position at angle 180° to the same. On the other side of the gyroscope casing, outside the corresponding bearing 16, is secured a cup 21, which is open at the side. Through the said opening is visible a mirror 22, secured by means of three screws 23, only one of which is shown in the drawing, to a part 24 on the bottom of the cup 21. This mirror is pressed outwardly by a spring 25 mounted in a bore of the part 24. By suitably setting the screws 23, the mirror may be brought into a position exactly at right angles to the axis $x—x$ of the gyroscope casing 9, or of the gyroscope body proper. The gyroscope body is not shown in the drawing. It is mounted in the usual manner within the gyroscope casing 9, on ball-bearings, which are provided in the pins 15. The cup 21, containing the part 24, is used for admitting lubricant, and the cup 26, which is provided on the plate 19, is intended for the same purpose. The cup 26 is further provided with a cock 27 through which air may be discharged from the gyroscope casing 9, or a light gas introduced into the casing for the purpose of reducing the surface friction of the gyroscope body. The instrument is closed by means of a sheet-metal cap 28, which is provided in front of the mirror 22 with an inspection opening 29.

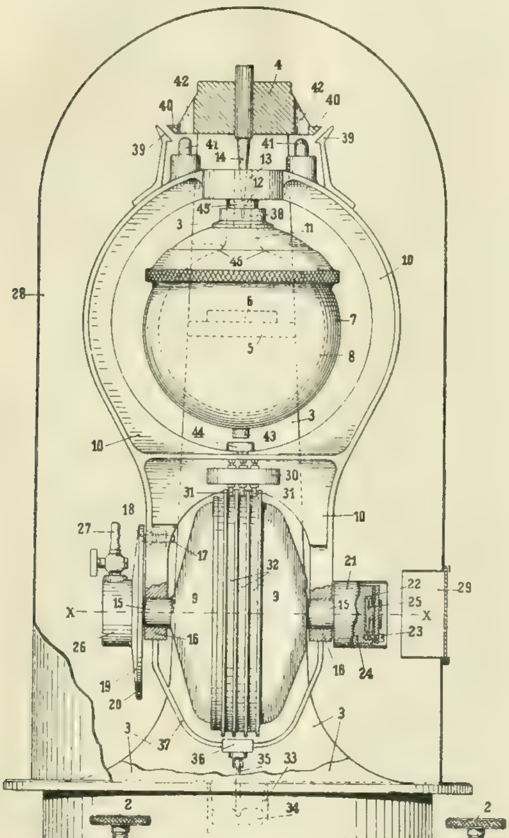
The gyroscope with the casing 9, bracket 10, and float 8, forms a floating system which can freely turn about the vertical axis and the geographical meridian. When the instrument has been steadied by hand to such an extent that only small oscillations take place, a reading can be effected with the assistance of the mirror 22. Then, as already stated, the gyroscope casing can be turned with the mirror to 180°, and the reading repeated, owing to which any errors in the setting of the mirror at right angles to the axis of the gyroscope are eliminated. Without this turning it is almost impossible to test the proper setting of the mirror if it is desired to keep the errors within the limits of one minute of arc or less. The securing of the mirror to the gyroscope casing presents the advantage that any changes of shape of the supporting bracket 10 and of the float 8 do not affect the reading.

The turning of the gyroscope casing with the mirror is of great importance. In order to do this, without interrupting the supply of current to the electric motor (in the construction illustrated a three-phase motor) driving the gyroscope body, the current supply is arranged in the following manner

The bracket 10 is provided with a brush-holder 30 on which are mounted three spring-controlled current-supply brushes 31. These slide on contact-rings 32 on the gyroscope casing 9, from which the three phases are supplied to the stator of an electric

motor, which is mounted in the gyroscope casing. The three phases are, however, supplied to the three brushes from the outside, without the free rotation of the floating system about the vertical axis being interfered with in the following manner.

On the bed-plate 1 is a mercury cup 33 containing the mercury 34. Into the latter dips a pin 35, which, by means of an insulating part 36, is secured to a member 37 depending from the bearings 16. Another mercury cup 38 is provided in the bore 12 of the neck 11, and into this dips the lower end of the centering-pin 14. Each of these two mercury



THE ANSCHUTZ GYROSTATIC SURVEYING COMPASS.

cups supplies one phase of current to one of the brushes 31, while the third brush is bodily connected to the bracket 10, and receives its current supply through the mercury in the vessel 7.

In order to make the instrument readily portable, on the bracket 10 are provided two spring-controlled hooks 39, which, when the whole bracket 10 is raised together with the float and the vessel, engage with corresponding projections 40 on the bracket 3, 4. Pins 41 on the bracket 10 engage then with suitable bores 42 of the bracket 3, 4, and a pin 43 engages with a suitable bore 44, also on the bracket 10, while at the same time the bottom end of the centering-pin 14 is enclosed fast by a half-ring 45 in the bore 12 of the neck 11. In that way the floating system is completely secured to the bracket 3, 4, while at the same time the upper opening of the mercury vessel 7 is tightly closed by the shoulder 46 of the neck 11. The instrument is therefore portable.

It is further pointed out that in the working position, between the circumference of the bottom end of the centering-pin 14, and the bore on the neck ring 45, there should be a clearance, in order not to disturb the free rotation of the instrument. This, however, does not affect the result of the reading, owing to the possibility of repeating the reading by turning the gyroscope casing with the mirror to an angle of 180°.

Indian Mining Laws.—In the *Journal of Indian Industries and Labour* for May, Sir Thomas H. Holland writes on the principles governing the grant of mining concessions in India. We give herewith his summary of the rules for the grant of prospecting licences and mining leases and we refer to his exposition of the principles in an Editorial.

Any British subject is at liberty to search for minerals in unoccupied and unreserved land which is the property of Government; but, before obtaining a prospecting licence or a mining lease, which carries with it certain privileges, he must obtain a certificate of approval from the local Government within whose jurisdiction the land lies for which the licence is required. A certificate of approval, which will hold good till the end of the calendar year, can be obtained for 50 rupees, and, if the local Government approve, can be renewed for a fee of 10 rupees.

The applicant for a prospecting licence is required to furnish a description of the land, illustrated by a map or plan, or alternatively, to peg out his claim according to a prescribed system; and when two or more applicants apply for the same land, the prior right to a licence, other circumstances being satisfactory, shall be deemed to lie with the applicant who first files his application with the Collector of the District.

Before a licence is granted the applicant must deposit either 100 rupees per square mile or part of a square mile, or give security to a like amount. The licence must then be executed within three months.

A district register of licences granted is open to inspection by any holder of a valid certificate of approval on payment of a small fee.

A licence is granted in the first instance for not more than one year, but may be renewed for a further term not exceeding two years.

The licensee has to pay a fee not exceeding one rupee and not less than one anna per annum per acre of the land taken up, and is required to pay royalty at a rate not exceeding 15% of the value on all precious stones that may be obtained, and, for other minerals over and above specified, small quantities allowed free, at the rates referred to below for mining leases.

The licensee requires the previous sanction of the local Government to transfer his rights to any other person holding a certificate of approval.

Within six months after giving up his licence, a licensee may be required to restore or to make safe any land opened up during his prospecting operations.

Each licence carries with it the right to claim a mining lease in accordance with the rules, the lease comprising the whole or a part only of the area covered by the prospecting licence, so long as the total areas leased does not exceed 10 square miles within any one province.

Before obtaining a refund of his security, a licensee may be required to disclose confidentially to Government any information obtained as to the mineralogical or geological nature of the area licensed.

In the case of mining leases, the applicant is required to deposit as security the equivalent of not more than 500 rupees, but any sum already held in deposit in respect of the prospecting licence will be carried forward to the applicant's account.

The application for a mining lease must be accompanied by a map or plan showing the boundaries of the area applied for ; or alternatively, the ground may be marked out as in the case of prospecting licences.

In the case of two or more applicants affecting the same land, not already held under a prospecting licence, the rule of priority holds.

A register of mining leases is kept in the Collector's office for inspection by holders of certificates of approval or their representatives on payment of a suitable fee.

No mining lease shall be granted by the local Government so as to cause the total area held under mining leases by the lessee or by those joint in interest with him to exceed 10 square miles within the territories administered by the local Government ; but the Government of India has power to grant areas in excess of this amount.

Without the previous sanction of the Governor-General in Council, or unless provincial rules are prescribed for special conditions, such as river dredging concessions, the length of an area granted under a mining lease shall not be allowed to exceed four times its breadth.

The boundaries below the surface of all areas given out on mining leases are regarded as running vertically downwards.

The term for which a mining lease may be granted shall not exceed 30 years, but the lease may contain a clause permitting renewal for another 30 years on a dead rent and surface rent not exceeding twice the original rents, the royalty payable being that which on the day following the expiry of the original lease shall be the royalty rate then in force.

A lessee, with the previous sanction of the local Government, can transfer his rights to another person or company holding a valid certificate of approval.

Unless prevented by reasonable cause, a lessee is required to commence operations within one year from the date of the execution of his lease, and is thereafter required to carry on the operations effectually in a proper, skilful, and mining-like manner. If a lessee, without reasonable cause, ceases to work the mine for a period not exceeding two years in such a manner as to produce sufficient mineral to earn a royalty at least equal to the dead rent, he will be liable to forfeit his leasehold rights, or may be required instead to pay a higher dead rent not exceeding twice the original rent.

A lessee is required to keep correct accounts showing the quantity of all minerals obtained, the number of persons employed, as well as plans of the mine, for Government inspection. He is required to allow existing and future adjoining licensees or leaseholders of land to have reasonable facilities of access thereto ; and is also required to report the discovery of minerals other than those specified in his lease

At the determination of his lease, he is required to deliver up the premises in a proper and workman-like state to the satisfaction of the local Government.

Any lessee is at liberty to relinquish his lease at any time on giving not less than twelve calendar months' notice and on payment of all sums that may be due, and cannot take a new lease for a portion of the land so relinquished.

The royalty rates prescribed by the rules include 5% on the sale value of ordinary coal, with a minimum of 2 annas per ton, and half these rates for coal dust. In the case of mica, the royalty is 5% on the sale value at the pit's mouth. For oil, the royalty is 8 annas per 40 gallons, or 5% *ad valorem* on the gross value ; and for gold and silver the rate paid is 7½% on the profits of each year taken separately, or 2½% on the gross value of the metal. Iron ore has hitherto been charged at the rate of half an anna per ton. Lease-holders for precious stones pay 30% on the net profits of each year taken separately ; and for all other minerals, not specified above, the rate is 2½% on the sale value at the pit's mouth, convertible at the option of the local Government to an equivalent charge per ton to be fixed annually or for a term.

Lease-holders are required to pay a minimum dead rent, which becomes absorbed by royalty. The minimum rates charged are four annas per acre for coal, lignite, and minerals used in agriculture and chemical manufactures, such as bauxite, gypsum, iron pyrites, and pyritous shales. For gold, silver, and precious stones, the minimum rate per acre is one rupee, and for iron ore one anna per acre. These minimum rates are liable to be exceeded according to the value of the deposit and the degree of the development of the area.

The annual surface rent charged for land actually occupied under lease is that assessable under the revenue and rent law of the province, or, if no such rent is so assessable, the rate may be fixed by Government, subject to a maximum on one rupee and a minimum of four annas per acre.

Origin of the Cost-book System.—At a recent meeting of the Royal Cornwall Polytechnic Society, Professor Henry Louis read a paper under this title, in which he gave an account of Roman tablets discovered in Portugal, these tablets containing inscriptions indicating the existence of a cost-book plan.

A few years ago it would have been hazardous to suggest that the cost-book system was a part of Rome's legacy to Cornwall, but an interesting discovery made in Portugal places this point beyond doubt. At the well-known argentiferous copper mines of Aljustrel, in Portugal, a bronze tablet had been discovered in 1876 beneath a heap of old slag, which gave some interesting particulars of the economic regulations that applied to these mines in Roman times. More recently, in 1906, a second tablet was discovered, the inscription on which shows the laws under which mining was carried on in this colony, and presumably also in others, and here it is interesting to note that we find the first traces of a well-developed cost-book system. The inscription dates from the reign of Hadrian. The relevant portions of the inscription may be translated thus :—

(2) Silver-bearing shafts shall be worked in the manner contained in this law ; the prices thereof shall be maintained according to the generosity of the most sacred emperor Hadrian Augustus, in such manner that the ownership of that share that shall belong to the Treasury shall belong to him

who first offers the price for the shaft and pays into the Treasury the sum of four thousand seterces.

(3) Whoever, out of five shafts, shall have sunk one down to the ore, shall work without intermission in the others, as is written above; unless he shall do so, others shall have power to occupy the same.

(4) If anyone, after twenty-five days given to preparation for the expenses, shall have forthwith commenced to carry out some work, but shall afterwards have ceased from working for ten successive days, others shall have the right of occupation.

(5) A shaft having been sold by the Treasury and having lain idle for six consecutive months, others shall have the right of occupying the same, provided that when ores are drawn from it one-half part shall, as is customary, be reserved to the Treasury.

(6) The occupier of the shaft shall be allowed to have such partners as he may desire, provided that the latter shall contribute to the expenses for that share by which he is a partner. Should he not do so, then he who has made the disbursements shall for three successive days in the most frequented part of the forum cause the account of the disbursements made by him to be published, and he shall intimate to the partners by the crier that each shall contribute to the expenses according to his share. Whoever shall not contribute, or with evil intent shall have done something so that he may not contribute, or shall deceive one or more of the partners, he shall be deprived of his share in the shaft, and the share of that partner shall belong to the other partners as they shall have paid the disbursements.

(7) And those colonists who shall have made disbursements in that shaft in which there shall have been several partners, shall be entitled to recover from their partners what shall be shown to have been expended in good faith.

(8) The colonists shall be allowed to sell among each other also such shares of the shafts as they may have bought from the Treasury and paid the price thereof, for as much as each one can obtain. Whoever wishes to sell his share or to buy one must make a declaration before the Warden in charge of the mines; it shall not be lawful to buy or sell in other wise. And whoever is in debt to the Treasury shall not be allowed to give away his share.

It will be seen that sections (6) and (7) really contain the essential regulations of the cost-book system; from the legal point of view nothing more is required, as we find here the power of making calls upon all the adventurers in a mine for expenses legitimately incurred and of forfeiting the shares of such of the adventurers as do not pay their calls. It is worth noting that such mining partnerships are to be met with wherever the influence of the Roman Empire can be traced, and that in a few cases they have survived up to the present time. The mining statutes of Trent, Iglesias, etc., all refer to it, and in Germany we have its survival, though in modified form, in the "Gewerkschaft," which was at one time almost identical with the cost-book company; we can even trace the introduction of the German terms, for in one of the Trent ordinances, dated 1214, we find the phrase "quattuor werki, silicet socii affidati." Again, the mining partnerships of the same type, as indicated in the Aljustrel Mining Law, are not known to modern Spanish Mining Law, but we find them set out with much detail in the mining laws of Spanish South America, which were derived from the Ordinances of Phillip II of 1584, which devote a section to mining partnerships, and enact regulations quite similar to the Roman ones though with more detail. A chapter of the modern Chilian Mining Law (Codigo de Mineria, 1888, Titulo XI, "De las Compañias Mineras") practically identical with that of the Argentine Republic of 1886, also includes a set of similar regulations.

There is thus excellent evidence that the principles of the cost-book system have come down to us direct from Roman times, and that it was the keen minds of Roman legislators that first devised this form of partnership, so admirably adapted to fostering mining enterprise.

The South-East Rand.—At a meeting of the Geological Society of South Africa held at the end of May, Dr. A. W. Rogers, Director of the Geological Survey of the Union of South Africa, read a paper entitled: "The Geology of the Neighbourhood of Heidelberg." Copies of papers read before the society are not available for general use until many months after they are read, so we take the following abstract of the paper from the *South African Mining and Engineering Journal* for June 4.

This paper describes the country between the Zuikerbosch Rand and the neighbourhood of Balfour. A coloured map accompanied the paper, on which the distribution of the rocks and the structure of the area were shown, and sections across the area were also exhibited. The most important result obtained in the demonstration was that each major subdivision of the Witwatersrand system diminishes in thickness southwards from the Rand, and that, in the country of which a geological survey has been made between the Klipriversberg and the Malan's Kraal–Tweefontein escarpment, there is no unconformity at the base of the Ventersdorp formation. The figures obtained for each major subdivision in Heidelberg are compared with the estimates made by Dr. Mellor on the Central Rand, and are as follows:—

	Central Rand.	*Heidelberg.*
	Feet.	*Feet.*
Kimberley-Elsburg series	6,120	3,560
Kimberley slates.......	500	370
Main-Bird series.......	3,160	1,020
Jeppestown series	3,700	3,000
Government Reef series	6,220	4,090
Hospital Hill series	4,900	3,180
	24,600	14,220

The Witwatersrand beds in Heidelberg are shown to be affected by many faults, and the relations between the faults and the many intrusions of igneous rocks are discussed in some detail. The most conspicuous dislocation, called the Sugarbush Fault, is later than most, if not all, of the minor faults, and later than most of the intrusions; it is an east and west fault which cuts off the Witwatersrand beds near Heidelberg from those near Balfour, and its throw diminishes westwards from at least 14,000 ft. near Eden Kop to some 3,000 ft. on Goedeverwachting, where it passes under the Karroo beds, which also conceal it beyond Eden Kop in the east.

The distribution of the conglomerates on each horizon on which they have been observed is described in the paper. Some of them are more persistent than others, and in general they are thinner and consist of smaller pebbles then the

conglomerates in similar stratigraphical positions on the Rand.

Certain strata in the Hospital Hill series, the Government Reef series, the Jeppestown series, and the Main-Bird series which possess characters rendering them valuable aids in addition to those already known for the purpose of correlating beds in more distant areas with the succession in Heidelberg, and through that with the strata on the Central Rand, are described in detail.

The paper also contained a discussion of the belief, prevalent in some quarters, that in Heidelberg the representative of the Van Ryn reef is to be found among beds which are regarded by the Geological Survey as lying above the Kimberley slates. It is shown that this belief is based upon incorrect data; that the maps published in support of it are inaccurate through errors in the position of outcrops of the Nigel horizon ranging from 500 yards to 6 miles having crept in; through the existence of important faults and large intrusions of igneous rocks having been overlooked; through the information to be got from the systematic and accurate record of position and dip of outcrops having been dispensed with; through the Bird amygdaloid on Maraisdrift and to the south of that farm having been mistaken for the Nigel slates; and perhaps through boulders of banket in the coal measure conglomerate having been mistaken for outcrops of banket in place. It is also shown that certain observations on cores from bore-holes, held by supporters of the erroneous correlation of Kimberley reefs in Heidelberg with the Van Ryn to prove that the Bird amygdaloid is an intrusive rock are wrong, and that the amygdaloid is a contemporaneous lava flow. It is also pointed out that the following assumptions made by the supporters of the erroneous correlation are mistakes: (1) a great unconformity at the base of the Ventersdorp formation, on account of which that formation in Heidelberg rests upon strata several thousand feet lower in the succession than it does in the Klipriversberg; (2) the persistence of character in individual beds of conglomerate on their several horizons wherever they are developed; (3) the existence of a fault between the Cason and Blue Sky shafts on the eastern side of which the beds are displaced towards the south, so that a reef with slate foot-wall in the east is brought into apparent continuity with a reef with quartzite foot-wall on the west. It is pointed out that the change in the nature of the foot-wall can be followed in detail, and that the reef is one and the same bed throughout.

Liquid-air Explosives.—The report of the Government Inspectors of Explosives for 1920 contains a brief reference to tests of liquid-air explosives. As is usual with Government reports the information published is meagre and non-committal, but we reproduce it herewith for what it is worth.

On October 8, 1920, experiments were carried out in Harefield Park, Middlesex, with liquid-air explosives, and were witnessed by two of the Government Inspectors. Representatives of the Admiralty, Board of Agriculture, and of county bodies were also present. The experiments were conducted by the Liquid Air and Rescue Syndicate, Ltd. The cartridges consisted of paper bags containing a carbonaceous absorbent material. A commercial No. 6 detonator was inserted and tied to the cartridge, which was then dipped into a container of liquid air. The liquid air had a high over 80% oxygen content. After being allowed to soak for about 15 minutes the cartridge was ready for use. The liquid-air container containing the cartridge was carried to the shot-hole, and as much as ten minutes were allowed to elapse between the time when the cartridge was taken out of the container and the firing of the shot. The cartridges with which the experiments were made were about 2⅜ in. in diameter and weighed about 2 lb. Single holes were bored under tree stumps about 18 in. in diameter without any other disturbance of the earth, and one 2 lb. cartridge was loaded and stemmed in each hole in the usual way. The shots were fired by electricity, and the results appeared to be satisfactory.

Sierra Leone Geology.—At the meeting of the Geological Society of London held on June 22, Frank Dixey read a paper entitled "The Norite of Sierra Leone."

The norite of Sierra Leone constitutes a complex of which the oldest and most important member is an olivine-norite. The complex forms the mountainous mass which, together with a narrow coastal plane of Pleistocene sediments, makes up the Sierra Leone peninsula. The norite was intruded in the form of a huge stock; it is thus very different from other well-known norites, which occur chiefly as laccolites or as special phases of larger masses of different composition. It does not appear to possess any marginal or basic modifications, while its junction with older rocks is obscured by the Pleistocene sediments. The complex is probably somewhat later than Pre-Cambrian in age, but in many respects it closely resembles certain well-known Pre-Cambrian masses. The main intrusion of norite was invaded in succession by the following related minor intrusions: (1) younger norites, (2) norite-pegmatite, (3) beerbachite, (4) norite-aplite, and (5) dolerite.

Important features of interest noted in the older norite are: (*a*) Well-developed flow-banding. (*b*) A series of binary and ternary intergrowths of the common minerals, indicating the importance of eutectic conditions during the crystallization of the magma. (*c*) Metamorphism due to the minor intrusions, which varies in intensity and character according to the nature and size of the minor intrusions. For instance, the younger norites and the beerbachite, not differing greatly from the older norite in composition, have caused extensive corrosion and even assimilation, but have not set up new minerals. The aplite and the dolerite, on the other hand, being relatively acid in composition, have, among other effects, converted the pyroxenes to amphiboles and modified the felspars. An interesting effect frequently observed in all phases of metamorphism of the norite is the recrystallization of part of the felspar and augite into graphic intergrowths.

The younger norites form two or more series of intrusions cutting the older norite, but they are collectively of small bulk as compared with the original intrusion. The field-relations of the older and younger norites are often very complicated, both on account of the irregular way in which the younger rocks have broken through the older, and of the extraordinary amount of corrosion and assimilation suffered by the older norite. The beerbachite intrusions are generally small and of irregular form; the larger intrusions actively disintegrated and incorporated the preceding intrusions of norite. The veins of norite-aplite generally occur

in the norite in the form of fine threads consisting mainly of quartz and micropegmatite. These threads, are, however, only the relatively-acid terminations of wider veins which are sometimes seen to attain a thickness of as much as 9 inches. The thicker portions of the veins consist chiefly of acid soda-lime felspar, orthoclase, quartz, and micropegmatite, with small quantities of pyroxene, hornblende, biotite, and apatite. The norite-aplite veins were succeeded by a series of more or less ophitic enstatite-dolerite dykes, free from olivine and rich in interstitial acid felspars. In many respects these dykes closely resemble the well-known British dolerites; they are, nevertheless, free from quartz and micropegmatite.

Iron ores occur in the norite as small masses up to several inches in length, as narrow schlieren, and as disseminated grains; they are highly titaniferous. Sulphides and other economic minerals often associated with noritic intrusions are rare or absent. The weathering and lateritization of the norite present some interesting features.

In the discussion following the reading of the paper, A. E. Kitson agreed with the view that the norite-mass had probably been intruded along a zone of faulting, and thus had determined to some extent the character of the coast-line of this part of West Africa. Since the norite-mass had not been foliated, he believed that it was later than Pre-Cambrian in age. The remnants of old platforms showed strong evidence of at least four successive uplifts, aggregating more than 1,000 ft. above sea-level. He agreed with the author that there had been a good deal of assimilation of the older norite by the younger intrusions. Examples of assimilation, though of different rocks, occurred in the Gold Coast. Although in the area between Freetown and the Hill Station there was a considerable amount of bauxitic laterite, he had not seen any blocks of bauxite.

The author, in reply, stated that iron ores occurred in the younger norites much as in the older norites, except that in the former they were present only as grains and small segregations, and not as schlieren. Also, bauxite occurred in small amount on outcrops of both the older and the younger norites.

SHORT NOTICES

Churn-drilling.—In the *Engineering and Mining Journal* for June 25, E. R. Rice commences an article on the churn-drilling of disseminated copper deposits.

Concrete Headgears.—The *Colliery Guardian* for July 1 and 8 contains a reprint of a paper read before the Liège Engineers' Association by C. Tournay on reinforced concrete headgears in France and Belgium.

Gold-dredge in Nevada.—In the *Engineering and Mining Journal* for July 16, G. J. Young describes the building of a gold-dredge at Dayton, Nevada.

Air-compressors. — The *Engineer* for July 22 publishes a report by Captain H. Riall Sankey on the Reavell quadruplex air-compressor.

Submersible Motors.—At the meeting of the North Staffordshire Institute of Mining Engineers, held on July 25, A. J. Ramsay read a paper on the application of submersible motors to mining work.

Galvanized Iron in Australia.—The *Industrial Australian and Mining Standard* for May 26 contains a description of the new works erected by John Lysaght (Australia), Ltd., at Port Waratah, Newcastle, New South Wales, for making galvanized-iron sheets. This company works in connexion with the Broken Hill Proprietary Co., and the technical skill is supplied by John Lysaght, Ltd., of Bristol.

Tungsten Filaments.—At the meeting of the Faraday Society held last month, C. J. Smithells read a paper on high-temperature phenomena of tungsten filaments, giving a record of some of his observations in the laboratories of the General Electric Company.

Estimation of Bismuth.—In the *Engineering and Mining Journal* for July 9, O. A. Critchett gives a new method of estimating bismuth in ores.

Lead Arsenate.—In the *Journal of Industrial and Engineering Chemistry* for June, O. W. Brown, C. R. Voris, and C. O. Henke describe a method of making lead arsenate by roasting a mixture of lead oxide and arsenious oxide.

Tellurium Alloys.—In *Chemical and Metallurgical Engineering* for July 20, J. H. Ransom and C. O. Thieme write on the effect of small quantities of tellurium in hardening and increasing the tensile strength of tin, lead, and white metal. It is believed that the action of the tellurium is to counteract the effect of other impurities rather than to form specific alloys.

Magmatic Differentiation.—In the *Journal of Geology* for June, J. H. L. Vogt commences an article on the physical chemistry of the crystallization and magmatic differentiation of igneous rocks.

Igneous Diffusion.—In the *Journal of Geology* for June, N. L. Bowen discusses diffusion in silicate melts.

Salt in Louisiana.—In the *Engineering and Mining Journal* for July 2, A. G. Wolf describes salt-mining operations in Louisiana.

Spitsbergen.—In the *Geological Magazine* for July Professor J. W. Gregory writes on the geological sequence across Central Spitsbergen from Advent Bay to Agardhs Bay.

Malayan Mining.—In the *Camborne School of Mines Magazine* for June, W. H. Eplett writes on lode mining in Malaya, giving particulars of work at Pahang, Bundi, Sungei Ayam, Intan, Sungei Gau, Menglimbu, Chendai, and Titi.

Peruvian Oilfields.—In the *Camborne School of Mines Magazine* for June, S. Raymond Prisk gives his "Impressions of an Oilfield", dealing particularly with conditions in Northern Peru.

Florida Phosphates.—In the *Engineering and Mining Journal* for July 16, S. L. Lloyd describes the method used in mining phosphates in Florida.

Gold Deposits in Peru.—The *Bulletin* of the Institution of Mining and Metallurgy for July contains a paper by A. Gordon Plews describing lode-gold deposits in the province of Pataz, Peru.

India's Hydro-electric Resources. — In the *Journal of Indian Industries and Labour* for May, J. W. Meares, electrical adviser to the Government of India, writes on the Government's policy with regard to the development of Indian hydro-electric power resources.

Colloidal Fuel.—*Engineering* for July 15 contains an article describing the use of colloidal fuel (that is, oil and pulverized coal mixed) at the works of the Steel Company of Canada, Toronto, for heating iron bars.

Carbocoal.—*Engineering* for July 29 gives further information relating to the Smith continuous carbonization process

NEW BOOKS, PAMPHLETS, Etc.

Copies of the books, etc., mentioned below can be obtained through the Technical Bookshop of *The Mining Magazine*, 724 Salisbury House, London Wall, E.C. 2.

Elements of Engineering Geology. By H. RIES and THOMAS L. WATSON. Cloth, octavo, 370 pages, illustrated. Price 22s. net. New York: John Wiley & Sons; London: Chapman & Hall, Ltd. This book is in the nature of a condensation of the author's well-known book, *Engineering Geology*, reviewed in these pages in September, 1914; or perhaps a better idea of its scope would be obtained if we said it was intended as a textbook for a shorter college course on the subject.

Claims against Mexico. By R. F. DESVERNINE. Cloth, octavo, 150 pages. Privately printed. This books consists of a brief study of the international law applicable to claims of citizens of the United States and other countries for losses sustained in Mexico during the revolutions of the last decade. The author is a member of the New York Bar.

History and Present Conditions of the Oil Industry in Galicia. By Dr. S. JANICKI. Pamphlet, 40 pages. Price 2s. 6d. net. London: The Polish Press Bureau, 2, Upper Montague Street, W.C. 1.

Canadian Geological Survey's Summary Report, 1920, Part B.—Pamphlet, 72 pages, with numerous maps. This report contains the following articles: the Mesozoic of the Upper Peace River, B.C.; Review of Prospecting for Oil on the Great Plains; The Great Slave Lake Area; Oil-bearing Rocks of the Lower Mackenzie River Valley.

Bulletins of Indian Industries and Labour. By Dr. J. COGGIN BROWN. Published by order of the Government of India. No. 2. Manganese Ores; No. 6, Antimony, Arsenic, and Bismuth; No. 7, Wolfram; No. 9, Chromite and Molybdenum; No. 11, Tin. These bulletins give brief outlines of the occurrence of the minerals, of their commercial uses, of the methods of identifying them, and of the customs in the metal and mineral trades.

COMPANY REPORTS

Transvaal Gold Mining Estates.—This company was formed by the late Nicol Brown in 1882 to acquire a group of gold-mining properties at Pilgrim's Rest, in the Lydenburg district of the Transvaal. In 1895 it was amalgamated with the Lydenburg Mining Estates, since when it has been in the control of the Central Mining group. The report for 1920 shows that 155,063 tons of ore was mined and treated at the Central mines, 17,790 tons at the Elandsdrift mine, and 21,414 tons at the Vaalhoek mine. The revenues, gross and per ton, including premium, were respectively £251,420 or 32s. 5d., £64,336 or 72s. 5d., and £45,021 or 41s. 7d.; and the total revenue was £360,778, equal to an average of 37s. 1s. per ton The profit was £89,751 or 9s. 2d. per ton. Of the total revenue, £89,358 accrued from premium, a figure almost identical with the net profit. The shareholders received £15,105, the dividend being at the rate of 2½%. Development has been restricted by the shortage of native labour. Another feature in connexion with development is that at the Central mines the assay-value of the ore continues to show a slight decline. The reserves are estimated as follows: Central mines 461,958 tons, averaging 7·58 dwt. per ton; Elandsdrift 73,650 tons, averaging 16·2 dwt.; Vaalhoek, 67,262 tons, averaging 8·64 dwt.

Rhodesia Broken Hill.—This company works the lead-zinc deposits at Broken Hill, Rhodesia, which were described in detail in the MAGAZINE for October, 1919. Edmund Davis is chairman and Hooper, Speak & Co. are the consulting engineers. During the year 1920 the amount of ore smelted was 42,806 tons, and the yield of lead 14,602 tons. The whole of this ore was obtained from the open-cut at No. 1 kopje. In course of mining, 46,423 tons of ore high in zinc was extracted also, and this has been dumped for future treatment. The study of the zincy ore has been continued, and an experimental electrolytic plant capable of producing 50 lb. of zinc per day is in operation. The prospecting and drilling work and the geological investigations have been continued, and useful information has been obtained with regard to the mode of occurrence of the ore-bodies. The cementation process has been successfully applied to the sinking of the shafts through the heavily watered dolomite. At the end of the year No.1 shaft was down to 151 ft. and No. 2 to 50 ft. The sales of lead during the year brought an income of £461,677, and £4,431 was received for vanadium ore. The net profit was £89,949, out of which £35,000 has been declared as dividend, being at the rate of 10%, less income tax. The output of lead during the first half of 1921 was 9,428 tons.

Eileen Alannah.—This company belongs to the Willoughby group and has worked gold mines in the Gatooma district, Rhodesia, since 1911. The ore is refractory, and there have been breaks in the continuity of operations. The report for 1920 shows that 21,720 tons was milled, yielding 4,788 oz. by amalgamating, grinding in pans, cyaniding of concentrate, and cyaniding of sand. The bullion realized £25,795. In addition a tributer extracted gold from accumulated slime, the royalty on which accruing to the company amounted to £130. The accounts show a loss of £1,950, bringing the total debit balance to £25,816. In February, 1921, there was an exceptionally heavy rainfall, as much as 9 in. being registered in a week. In consequence the workings were flooded to near the surface. The pumps have so far made little impression on the water, and it is possible that the property may be abandoned, for the present at any rate. Perhaps the oxidized ore in the open-cuts may be worked, if not the sulphides below.

South Kalgurli Consolidated.—This company was formed in 1913 to amalgamate the South Kalgurli and Hainault gold mines at Kalgoorlie, West Australia. The report for 1920 shows that 80,270 tons was milled for a yield of 30,915 oz., equal to 7·7 dwt. per ton. The par value of the gold was £130,992, and £51,284 was received as premium. The net profit was £36,344, out of which £31,250 is being paid as dividend, being at the rate of 25%. The ore reserve is estimated at 179,900 tons, together with a probable 88,100 tons. Development is still being actively continued, though no new discovery of note has been made since that of June, 1919, which, as John Morgan, the consulting engineer, says, was so effective in raising the general grade of the ore treated.

Associated Gold Mines of Western Australia.—This company was formed in 1894 to work the Australia leases at Kalgoorlie. Of recent years the ore has been of low grade and no dividends have been paid since 1914. The report for 1920 shows that 64,462 tons of ore was treated for a yield of gold realizing £121,614, of which £35,439 accrued from premium. In addition £5,174 was received as royalties from tributers. After writing off the cost of development and diamond-drilling, a profit of £25,624 was made. From this is deducted £8,864, the adverse balance brought in from the previous year, leaving a credit balance of £16,760. D. F. McAulay, the manager, states that exploratory work has proved the continuance of the Australia East lode in depth. The company holds interests in the Keeley Silver Mines and the Porcupine V.N.T. companies operating in Canada. The former started milling recently, but nothing is being done at the latter owing to the continuance of high costs.

Lake View & Star.—This company was formed in 1910 to amalgamate the Lake View Consols and the Hannan's Star companies, after the former had ceased to be a great producer. In 1915 the Chaffers mine was purchased. During the year 1920 the ore raised and treated amounted to 95,157 tons, and the yield of gold was 25,541 oz., the par value of which was £108,881. Gold premium and a small amount of royalty received from tributers brought the income to £168,489. The working profit was £27,494, of which £3,000 was written off for depreciation and £22,500 was paid as dividend, being at the rate of 11¼%. Developments during the year have not given any results at Lake View or Hannan's Star, but additional ore has been disclosed at Chaffers. The main shaft at Lake View has been sunk deeper in order to open a new level at 2,300 ft. The ore reserves are estimated as follows: Lake View, 58,589 tons, averaging 28s. 9d. per ton; Hannan's Star, 178,453 tons, averaging 25s. 8d. per ton; and Chaffers, 5,400 tons, averaging 40s. 4d. per ton; all par values.

Oroya Links.—This company was formed in 1896 as Golden Link Consolidated to acquire properties at Kalgoorlie. In 1909 the name was changed and milling plant was acquired from the Oroya Brownhill company. Operations were suspended in 1916, and part of the property has been let on tribute. J. H. Cordner-James is chairman, and Bewick, Moreing & Co. are the general managers. The report for 1920 shows that the tributers extracted 13,137 tons of ore, and that 5,765 tons of ore was purchased. The net profit was £2,537, which was carried forward.

British Broken Hill.—This company was formed in 1887 to acquire Blocks 15 and 16 at Broken Hill, New South Wales. The report now issued covers the year 1920. The mine and dressing plant were closed on account of the strike for 19 months. Mining was resumed on November 16, 1920, and from then until the end of the year 660 tons of carbonate ore was raised, averaging 28·5% lead and 5·3 oz. silver per ton; also 13,756 tons of sulphide ore, averaging 12·8% lead, 11·8% zinc, and 7·3 oz. silver. The lead concentrator treated 14,279 tons, and produced 2,330 tons of lead concentrate, averaging 60·7% lead, 7·3% zinc, and 26·4 oz. silver. At the zinc flotation plant 10,636 tons of lead-mill residue, averaging 12·6% zinc, 3% lead, and 3·1 oz. silver, was treated, yielding 2,120 tons of zinc concentrate, averaging 45% zinc, 9% lead, and 10·8 oz. silver. After the turn of the year the fire at Port Pirie smelting works and the general adverse conditions made it necessary to stop work at the end of January. The accounts for the year showed a loss of £47,757. The reserve of sulphide ore is estimated at 1,057,905 tons, averaging 12·4% lead, 11·3% zinc, and 6·9 oz. silver.

Briseis Tin & General Mining.—The company has worked alluvial tin deposits in north-eastern Tasmania since 1899. The report for 1920 shows that 181,981 cu. yd. of ground was treated at Briseis, [illegible] a yield of 219·8 tons of tin concentrate, the extraction per yard being 2·72 lb., while at Ringarooma 115,500 cu. yd. yielded 23·5 tons, being at the rate of 0.45 lb. per yard. The total production was 244 tons. This was smelted at the company's works at Launceston, and the metal obtained, 176¼ tons, sold for £46,155. The working profit was £15,467, out of which £2,229 was written off for depreciation, and £7,368 was allowed for British and Colonial taxes. Arrangements are being made for diverting the Ringarooma river once more to bring it behind the working faces by means of a high embankment. Until this work is completed the output of tin concentrate will be necessarily restricted.

Kramat Pulai.—This company belongs to the Tronoh group, and was formed in 1907 to work alluvial tin properties at Pulai, in the Kinta district of Perak, Federated Malay States. Subsequently deeper leads containing scheelite were worked, according to the demand for this mineral. A year ago it became necessary to provide rock breakers for disintegrating the scheelite-bearing material. The report for 1920 shows that the output of tin concentrate was 112 tons and of scheelite 194 tons. The production of scheelite was suspended in September owing to the low price obtainable. The accounts show receipts of £34,326 from the sale of the company's products and of £4,289 from tributers. The net profit was £15,194, and, with the amount brought in from the previous year, the credit balance on December 31 was £24,937. Dividends absorbing £20,000 have been paid, being at the rate of 20%.

Gurum River (Nigeria) Tin Mines.—This company was formed in 1911 to work alluvial tin property in the north-western part of the Bauchi plateau, Nigeria. Oliver Wethered is chairman, J. M. Iles is on the board, and Laws, Rumbold & Co. are the general managers in Nigeria. The report for the year ended September 30, 1920, just published, shows that the output of tin concentrate was 176 tons, as compared with 104 tons the previous year. The receipts from the sale of concentrate were £21,353, and the net profit was £2,923. Adding £14,010 brought forward from the previous year, the disposable balance was £16,934. Out of this £12,316 has been distributed as dividend, being at the rate of 15%.

Naraguta Extended (Nigeria) Tin Mines.—This company has worked alluvial tin ground in the northern part of the Bauchi plateau, Nigeria, since 1911. The report for 1920 shows that the output of tin concentrate was 224 tons, as compared with 276 tons the year before. The fall was due partly to labour shortage, but also to the supply of water during the rainy season not being up to the average. The accounts showed a credit balance of £359 for the year's working. At the present time the property has been let on contract.

Kaduna.—This company was formed in 1910 to acquire alluvial tin properties on the western side of the Bauchi plateau, Nigeria. J. E. Snelus is the manager. The report for the year ended October 31 last shows that the output of tin concentrate was 168 tons, as compared with 205 tons the year before, the fall being due to the shortage of efficient native labour. The accounts show credits of £21,361 from the sale of tin, and a loss for the year of £482. The sum of £3,699 was brought forward from the previous year, and £7,360 was recovered from excess profits tax previously paid. The balance in hand was therefore £10,576, out of which a dividend at the rate of 10% was paid, absorbing £2,780. Additional prospecting licences have been acquired during the year.

Kaduna Prospectors.—This company was formed in 1913 as a subsidiary of the Kaduna Syndicate, and now works alluvial tin property in the southern part of the Bauchi plateau, Nigeria. The report for the year ended October 31 last shows that 90¾ tons of concentrate was won, as compared with 58½ tons the year before. The accounts show a loss of £750. Additional ground is now being examined under prospecting licence.

Burma Ruby Mines.—This company has worked ruby mines at Mogok, Burma, since 1889. During 1920 the amount of earth washed was estimated at 771,406 truck-loads and the stones recovered were valued at £43,010. The sales brought an income of £33,507. There is a steady demand for the ordinary qualities of stones in India and Burma, and fine stones are always in demand in London and Paris. Large sections of ground are worked by tributers, and the royalties collected during the year amounted to £14,528, which, less cost of collection, was handed over to the Indian Government. The accounts for 1920 show an adverse balance of £5,929. During the year sluicing has been introduced, and water is now brought in instead of the earth being hauled to the washers. In this way the cost of operation will be greatly reduced.

Poderosa.—This company was formed in 1908 to acquire copper properties in the Collahuasi district, Chile. The ore is of high grade, but conditions of work are difficult; moreover, the marketing of the ore has been subject to frequent interruptions during recent years. Dividends were paid for 1909, 1916, and 1917. The report for 1920 shows that 5,011 tons of ore, averaging 30·13% copper and 15·16 oz. silver per ton, was shipped to the smelters, as compared with 1,498 tons of similar tenor the year before. The operations during the first three quarters of 1920 were fairly remunerative, but with the fall in the price of copper it became impossible to ship at a profit, so that since October work has been confined almost entirely to development. The accounts show receipts £108,620 from the sale of ore and a profit, after allowance for development and depreciation of plant, of £18,349, out of which £8,750 has been distributed as dividend, being at the rate of 2½% less income tax. R. O. Packard, the manager, gives particulars of current and projected development. He estimates the ore in the Poderosa mine ready for shaping at about 10,000 tons, averaging 25 to 30% copper, and the concentrating ore on the dumps at 134,000 tons, averaging 3½% copper.

Libiola Copper.—This company has worked a copper mine in the north of Italy since 1888. The report for 1920 shows that the yield of copper ore was 2,297 tons and of pyrites 6,309 tons. The demand for cupreous pyrites improved during the year. Owing to labour unrest, operations were on a comparatively low scale, and no development work was done. The reserve is estimated at 6,325 tons of copper ore and 37,560 tons of pyrites. The profit and loss account shows a credit balance of £234.

The Mining Magazine

W. F. WHITE, *Managing Director.* EDWARD WALKER, M.Sc., F.G.S., *Editor.*

PUBLISHED on the 15th of each month by THE MINING PUBLICATIONS, LIMITED, AT SALISBURY HOUSE, LONDON WALL, LONDON, E.C. 2.

EDITORIAL

THE Engineers' Club was formally opened on September 1. The Club occupies a handsome house at the corner of Coventry Street and Whitcomb Street, between Leicester Square and Piccadilly Circus. The honorary secretary is Mr. E. L. Hill.

ONLY last month we referred with commendation to Sir Thomas Holland's services in the administration of certain branches of Indian Government business. It is unpleasant, therefore, to have to record that he has had to resign his position as member for commerce on the Council of the Governor-General of India. He ordered the abandonment of a prosecution, which the legal members of the Government considered should be continued. Here, again, it is of little avail to plead that his actions were prompted by notions of public duty. We can only express regret that his undoubted abilities and his sympathetic methods of handling native questions should be lost to the Government at a time of anxious national stress.

ONE of Mr. E. H. Clifford's recommendations relative to winding from great depths, contained in his paper on the City Deep mine read before the Institution of Mining and Metallurgy early this year, was that cages and skips should be made of the strongest steel or other alloy obtainable, in order that their weight should be reduced to the lowest possible limit. It is obvious that the lightening of the hoisting load obtained thereby would effect an important economy and substantially reduce the working costs, in spite of the fact that the first cost would be considerable. We hear, however, that inquiries made by mining houses do not receive a ready response from the constructional engineers, who appear to be rather doubtful as to the advisability of such a policy. We can assure the manufacturers that the matter is one well worth their attention.

IN memory of Thomas Newcomen, the pioneer of steam engineering, a monument has been erected in his native town of Dartmouth, being placed in the public park facing the River Dart. The monument consists of a large, rough-hewn granite block, to which is affixed two brass tablets. One of the tablets gives in a few words an outline of Newcomen's career, and on the other there is an engraved representation of his invention, the atmospheric steam engine. Newcomen was born in Dartmouth in 1663, where he first earned his living as a blacksmith. The house he lived in was in existence until 1884. The records show that he built an engine near Dudley Castle in 1712, and the last that was at work was at the South Liberty coal mine near Bristol. He died in London in 1729, and he was buried in Bunhill Fields cemetery, which is situated about half-way between the old and the new homes of the Institution of Mining and Metallurgy.

AT the annual meeting of the Cornish Chamber of Mines, certain members forcibly expressed their disapproval of words in the editorial on Cornish Conditions appearing in the MAGAZINE last month. The offending words were : "Cornish mining is dead." Without their context and without further amplification the statement appears sufficiently alarming. But the word "dead" is one of elastic definition, as will be found by reference to the Oxford Dictionary. We did not mean it in the sense of Artemus Ward's "killed fatally dead," but rather in the mode of language of the stockbroker, who at present loudly avers that the rubber share market is "dead." "Inactive, motionless, idle," are given in the Oxford Dictionary, and this is the sense in which it was used by us. A more considered phrasing of the words and their context would be : "Cornish mining is temporarily dead, and there are no signs of an immediate revival." Mr. R. Arthur Thomas at the meeting put it concisely when he said : "Cornish mining is not dead, but sleepeth."

Carbonic Oxide Poisoning

On several occasions recently we have drawn attention to the dangers arising from the gradually extending use of carbonic oxide in metallurgical and other industrial and domestic operations. Owing to it being without colour and odour, its presence is not detectable until unpleasant physical symptoms arise, and for the same reason the symptoms are not easily recognizable as the result of this particular form of gas

poisoning. In mining operations its effect is not as generally understood as it should be, and the headache following exposure to the fumes of blasting is often wrongly attributed to nitrous compounds. Though various writers have given the results of their investigations into the composition and effects of the fumes given off by explosives, the action of carbonic oxide has not received the attention it deserves, owing presumably to the comparatively small proportion present. One of these days a medical man will devote himself to the study, in the same way as Dr. Leonard Hill has made a speciality of the effects of moisture in hot atmospheres. The remedy will probably lie in regulation of times of blasting, rather than in the matter of ventilating, but the subject will afford considerable scope for investigation. In coal-mining the gas is known as "white damp," but the effect of its presence after an explosion of coal gas or coal dust is often ignored, and it is only recently that the necessity for providing means for combating its effect during first-aid and rescue operations has been recognized.

The dangers arising in industrial operations from the use of commercial gases containing carbonic oxide, and from its incidental formation and escape, are fully understood by the Home Office, for a number of publications have been issued dealing with various phases of the subject. One of these was issued last month by the Factory Department, entitled "Memorandum on Carbonic Oxide Poisoning in Factories." This pamphlet contains a large amount of information of value to metallurgists and to users of gas engines and plant in which gas is employed for heating purposes. At so many mines and metallurgical works gas is used nowadays that this pamphlet ought to be in the hands of all our readers. It is not possible here to give anything like full quotations, but one point raised is deserving of special reference. The dangers are often entirely unsuspected, and in the specific case mentioned deaths have been known to occur owing to the slow smouldering of coal and other carbonaceous matter in dumps. The gases released by this action permeate the soil and gain access to buildings. In the same way gob fires in coal mines are dangerous, for this reason as well as on account of the heat evolved, though in these cases the ventilating current usually provides sufficient remedy.

In factories and mines it is possible, by observing certain rules, to keep clear of the dangers of carbonic oxide, and in well-organized establishments there are means for instantly combating its effects when the symptoms arise. Under these conditions there seems no reason for agitating against the use of gases containing this highly poisonous constituent. On the other hand, the increasing proportion of carbonic oxide in town gas used for household purposes is open to considerable objections, and the recent report of a Board of Trade committee refusing to recommend a limit must be viewed with some disquietude. The battle of twenty-five years ago between the water-gas fraternity and the anti-poison group will be remembered. The result at the time was a curbing of the general expansion of the use of this gas, but two factors in the problem have since arisen to change the point of view. In the first place the incandescent mantle requires heat and not illuminating power in the gas employed, while the gas-works desire an outlet for their coke. Thus the Gas Regulation Act, passed a year ago, allowed the gas companies to sell gas by heating power instead of illuminating power, and they were given a free hand with regard to carbonic oxide content, subject to the decision of a committee appointed by the Board of Trade. This committee met a great many times, and examined a number of expert witnesses. The opinions expressed differed fairly widely, but the general view appears to have been that as straight coal gas contains 9% of carbonic oxide, there can be no serious objection to higher proportions being used. While many experts pressed for a maximum of 20%, the preponderating view was that no limit should be imposed. It cannot be denied that the members of the committee and the experts are well informed men, but the average user of gas feels that their judgment is open to criticism, and that there is something wrong somewhere. The gas companies claim that they are benefactors to the race because their product gives no smoke and no fumes to destroy buildings; they must not object if they receive a retort to the effect that they introduce a virulent poison into our houses. There is reason to doubt the sincerity of the altruistic attitude assumed by the lighting and heating corporations, for are not the electric lighting stations the worst offenders in the matter of discharging black smoke into the

atmosphere. The cynic will go almost as far as to say that these clouds of smoke are good for the companies, as they create a demand for artificial light. Seriously, however, the carbonic-oxide position is unsatisfactory, and much has still to be learnt by producers, users, and experts. Watch will undoubtedly be kept on the results of the recent removal of restrictions, and the matter will be revived at a later date. As far as this MAGAZINE is concerned, it is impossible to do more now than to question the wisdom of allowing unlimited use of this gas.

The Metalliferous Mines Advisory Committee

As mentioned in the June issue, the Secretary for Mines recently appointed an Advisory Committee for the Metalliferous Mining Industry. No doubt many readers are sceptical of the value of any departmental committee, and judging by past experience they have good reason for such disbelief, for the permanent or political Government officials have usually ignored the recommendations of such advisers. But this attitude of scepticism is surely wrong, for everybody connected with metalliferous mining in this country should endeavour strenuously to back their interests and take full advantage of the opportunity now offered for doing some good to an industry which is confessedly in a parlous position. Anyway, most of the committee take a serious view of their duties, and they should be generously supported in mining circles. Among the members of the Committee best known to readers of the MAGAZINE are Dr. F. H. Hatch, Dr. Malcolm Maclaren, Professor Henry Louis, and Messrs. Frank Merricks, F. W. Harbord, R. Arthur Thomas, Anthony Wilson, and T. C. F. Hall. The committee consists essentially of representatives of owners of iron, tin, and other metalliferous mines, and of an equal number of representatives of labour, together with mining engineers, geologists, and metallurgists, and a medical expert. If there is a criticism to be made with regard to the constitution of the committee it arises from the appointments to the chairmanship and vice-chairmanship. Sir Cecil Budd is the chairman, and it is generally felt that this office would have been better held by some one conversant with mining rather than by a representative of the metal markets; while it is considered in some quarters that the presentation of the vice-chairmanship to the Labour party gave the Committee too much of a political complexion. These points are not of any great practical importance as matters go nowadays, and it is well to dismiss the criticisms as promptly as possible. The great point in connexion with the Committee is that its formation marks a new era in administration, and that for the first time in our history the owners and workers have a direct and legitimate voice in such control as is exercised by a Government department. The Committee has the widest functions, and though the Minister is not compelled to refer any question to it, undoubtedly he will have in practice to obtain the opinion of his advisers. It is also laid down in the constitution of the Committee that the Minister " shall take into consideration any representations which may be made to him by the Committee," a clause which gives a right that may prove to be of immense value to the industry. As regards recommendations involving the spending of money, the Committee was told at its first meeting that the limit of expenditure by the Mines Department had already been reached, so that no such recommendations could be considered. This, of course, excludes a great many matters that would otherwise have been brought forward, and has accordingly caused much disappointment to a large section of the non-ferrous mining community.

One of the recommendations already made by the Committee relates to the collection of statistics of production and labour. Of recent years the Home Office reports on these matters have grown more and more absurd, as regards both scantiness and dilatoriness of publication. The mine owners send full returns in January, and an ordinary business house would be able to publish the reports in February. But the reports are generally published towards the end of the year, when they are of little use to those engaged in the industry or to anyone else. The Committee is now urging a reform in this method of presentation of the returns, and is also urging their publication, especially those relating to labour, at shorter intervals, say quarterly.

The Minister of Mines has placed before the Committee the recommendations of the various Commissions that have examined the conditions of the mining industry of late years, in particular the Royal Commission on Metalliferous Mines and Quarries,

the Royal Commission on Royalties, and the Departmental Committee on the Non-Ferrous Mining Industry. Up to the present time no effort has been made to carry out these recommendations, and the various reports have been entirely neglected. They are now being considered by the Committee, and it is probable that many of the recommendations contained in them will be endorsed by the Committee, and probably accepted by the Minister. It will hardly be possible to deal with all these matters by immediate legislation, and in any case there is great difficulty in drafting an Act of Parliament in a sufficiently comprehensive manner to include all the regulations that would be necessary, so in all probability the most urgent matters will be dealt with by means of special rules and Mines Department regulations, which, when formally issued, have all the force of law. In preparing the rules, it is of importance that they should be adapted to each class of metalliferous mining, for it is clear that what is suitable for open-cut ironstone mining in the Midlands is not easily adaptable to tin-mining operations. Then, again, local nomenclature should be considered, for the terms used in the various districts differ widely. Even in Furness, the words and their meanings are not all identical with those employed in the neighbouring iron mines in Cumberland, while Cornwall has a dialect of its own. Sub-committees have already been formed to consider the qualifications of managers, the keeping of plans, the rules for safety and health, and other subjects.

Probably the question of royalties, way-leaves, and rates will receive close attention by the Committee. It is to be hoped that the new statistical returns will give the information, which has hitherto been unavailable, relating to the amounts paid by the mines under these headings. Curiously enough, the Royal Commission on Royalties was unable to secure exact data, a fact which went far to nullify any good done by the inquiry. The Government is pledged to the nationalization of royalties, and it is clear that full details must be obtained before any legislation can be undertaken. Both mine owners and the workers are aware of the heavy handicap of these charges, and are equally helpless in the matter. It is true that occasionally a royalty owner will alleviate the burden under special circumstances, but nothing but public regularization will really meet the case.

3—3

It will therefore be one of the duties of the Committee to advise as to the terms of nationalization. The incidence of local rates is not of less importance than the imposition of royalties, and it will also receive due attention.

The Committee has started well, and it will no doubt make its position felt. Outside support must be given to it so that it shall be able to avoid the fate of similar bodies, which have gradually sunk into the apathy consequent on neglect. It must not stop at mere advice on official proposals, but should boldly handle all the factors that have so largely contributed to the existing desperate position. We may hope that the Minister of Mines will make full use of the Committee, and treat its recommendations with sympathy and intelligence, and give it a status that will encourage it to throw itself with energy and responsibility into the task before it.

Shetland Copper

As recorded in recent issues, a project is in hand for the reopening of the old copper mines in the Mainland of the Shetland Isles. At the time we recommended inquirers to consult Dr. J. S. Flett, director of the Geological Survey, with regard to this subject. Since then a report by Dr. Flett has been issued by the Scottish section of the Geological Survey, giving a historical account of these ore deposits, so the public are now in possession of all essential details.

The deposits are found in the Old Red Sandstone of the Devonian Age. These rocks are principally conglomerates, red sandstones, and shales, with occasional thin-bedded grey flagstones. The area covered by the rocks extends from Rovey Head, a few miles north of Lerwick, the capital of the Isles, along the eastern side to Sumburgh Head, at the extreme south of the Mainland. To readers of Sir Walter Scott the country will be familiar as providing the principal scenes in " The Pirate." Pyrites and chalcopyrite are found in lodes in these Old Red Sandstone rocks, and at a number of places these lodes have been worked for copper at various times. The most important of the operations have been at Sandlodge, which is situated about 14 miles south of Lerwick. The lode trends about N. 10° E., and three old shafts are marked on the 6 in. ordnance survey map. The country rock is reddish sandstone, and the weathered back of the lode can be seen in some old pits. The

lode consists largely of siderite, which is weathered to limonite on the surface to a depth of about 100 ft. The pyrites is found in stringers and pockets, and other sulphides, such as galena and blende, are also present. The deposit was originally worked for copper ore, but at one time iron ore was also mined. In depth the siderite gives place partly to carbonates of lime and magnesia. The lode is fairly wide, measuring 9 or 10 ft., and there is also a subsidiary lode. The foregoing facts give a general idea of the nature of the deposit, but it is interesting also to record the history of the work done.

The early records indicate that the Sandlodge mine was first opened toward the end of the eighteenth century, and that a party of miners was brought over from Wales to do the development. Shafts were sunk, and copper ore was raised, selling for about £2,000. The death of the lessee put an end to the operations before much work was done, but by the year 1800 mining had been resumed. Robert Jamieson, in his *Mineralogy of the Scottish Islands*, describes his visit to the property in 1799. According to his account, two lodes had been worked, known as the east and west veins, and forming branches of one lode. In 1803 Patrick Neill was there, and he gave his impressions in his *Tour through some of the Islands of Orkney and Shetland*. He found that a shaft was down to 130 ft., and that one or two cargoes of dressed ore had been shipped. He was told that the company had spent £10,000 on the mine, and that the best quality of picked ore realized £70 per ton. John Sherriff, in his book *A General View of the Shetland Islands*, published in 1817, mentions that Professor Fleming visited the district in 1808. The mine had been abandoned by that date and the shafts were full of water. From time to time during succeeding years the property was worked on a small scale with unimportant results, and it was not until 1872 when John Walker obtained a lease that public attention was attracted once more. Mr. Walker carried on work actively for eight years, and raised about 10,000 tons of iron and copper ore. In 1878 the production of copper ore was 708 tons, valued at £1,770, and of iron ore 1,241 tons, while in 1880 the yield was 1,995 tons of copper ore valued at £5,814 and 396 tons of iron ore valued at £344. Mr. Walker sold the lease in 1880 to the Sumburgh Mining Company, which had a nominal capital of £60,000, but this company went into liquidation in the following year. Since then the property has been examined on many occasions, but reopening was never recommended, until in November last the present enterprise was inaugurated.

One of the most enlightening accounts of the deposit written in recent years is found in a paper read in 1908 by Mr. R. W. Dron before the Geological Society of Glasgow, entitled "Iron and Copper Mining in

Geology of South of Mainland of Shetland Isles.

Shetland." He gives some idea of the nature of the deposit and of the ores mined. He states that the lode averaged 9 or 10 ft. wide and that the west shaft had been sunk on the incline to a depth of 180 ft. For the first 100 ft. the lode appeared to have consisted of hematite and limonite, the weathered products of siderite, with here and there pockets of copper pyrites. He was informed that the iron oxides had been shipped to gas works for use as a desulphurizer. Below the 100 ft. level, he reported the lode material to be siderite, associated with carbonates of iron and

magnesia, and that this also contained copper pyrites. Also he mentioned that a vertical shaft had been sunk to cut the main lode at a depth of 240 ft., and that below this point the shaft had followed the lode for 60 ft., and levels driven northward and southward for 220 ft. and 190 ft. respectively. In these bottom workings the lode material is reported to be white siderite, containing copper pyrites, but Dr. Flett is of opinion that its composition is vary variable.

Dr. Flett in his report mentions a number of other spots where copper pyrites is known to exist in this district. At Setter, about half a mile south of Sandlodge, a lode has been known for many years, and an attempt was made to work it in 1890. Two shafts were sunk. One of these was near the coast line, and followed the lode for 90 ft. The vein was of solid copper pyrites, but it was narrow, being only a few inches wide at the surface and 15 to 20 in. at the deepest point worked. The proximity to the sea made it impossible to continue the sinking of the shaft, so a second shaft was started about 150 ft. inland, and on higher ground. This shaft was sunk to 83 ft., and a cross-cut was then started to intersect the vein, but at this stage the venture was abandoned. Copper pyrites is also found on the cliffs at Sandwick and No Ness, not far from Sandlodge, and the lode is presumably a continuation of that worked at Sandlodge. Other trials have been made at Levenwick, Hoswick, Garthness, and Quendale. Fair Isle, situated about half-way between Orkney and Shetland, belongs also to the Sumburgh estate, and here there is another outcrop of copper pyrites, which has been investigated at various times during the last hundred years, but neither its nature nor its position has been such as to encourage exploitation.

From the description of these deposits it would appear that they resemble more or less closely the siderite lodes north of Perranporth, Cornwall, to which attention was drawn in these pages about four years ago. They do not seem to afford much hope for success. Dr. Flett says it is quite possible that with modern methods of mining and dressing there may still be a future for the Sandlodge mine, but this is evidently more of the nature of a polite reservation than an actual opinion. For ourselves we do not consider that the project of reopening this mine is a suitable subject for paragraphs in the financial dailies.

Reference is made in the foregoing article to Sir Walter Scott's romance "The Pirate," in which many of the scenes are placed in Shetland. In the course of the story, he makes mention of the copper deposits, and as the account given is appropriate to the present position, we give extracts herewith.

One of the characters in the story, Triptolemus Yellowley, is continually attempting to introduce so-called improved agricultural methods into the islands, and is the author of many other similarly inconsidered schemes, the results always being disastrous. He has a sister who is the meanest of the mean, but also an acute critic. On a certain auspicious occasion he is congratulating himself on the bonny blaze of wood on the hearth, to which his sister retorts that he won't see such a blaze again unless the house takes fire or a coal-heugh is found.

"And wherefore should not there be a coal-heugh found," said Yellowley triumphantly, "I say, wherefore should not a coal-heugh be found in Shetland as well as in Fife [from whence he came], now that the Chamberlain of the Isles has a far-sighted and discreet man [himself] upon the spot to make the necessary perquisitions."

"I tell you what it is," answered his sister, who had practical reasons to fear her brother's opening on any false scent, "if you promise the Chamberlain so many of these baubles we shall not be well settled here before we are found out and set trotting again. If one was to speak to you about a gold mine, I know well who would promise he should have Portugal pieces clinking in his pouch before the year went by."

"And why should I not," said Triptolemus, "maybe your head does not know there is a land in Orkney called Ophir, or something very like it; and wherefore might not Solomon, the wise King of the Jews, have sent thither his ships and his servants? Yes, you shall all of you see what a change shall coin introduce, even into such an unpropitious country as this. Ye have not heard of copper, I warrant, or of iron-stone, in these islands, neither? There is copper near the cliffs of Konigsburgh; ay, and a copper scum is found on the Loch of Swana, too."

And so on. It should be added that Yellowley was not the pirate which provided the title to the story. Eventually Yellowley has to drop his schemes as the inhabitants are derisive of his failures.

REVIEW OF MINING

Introduction. The metal markets continue to be very dull, and consequently mining remains in the doldrums. The trade of the country is, however, tending to improve, following resumption of operations on the conclusion of the coal strike. Thus there is a rather more hopeful feeling in mining circles.

Transvaal.—The agreement reached last month between the Chamber of Mines and the men's unions for a cut in wages of white labour, depending on cost of living, has already had a brightening effect on the gold shares, and in both Johannesburg and London the quotations have recovered slightly from the low level to which they had sunk. The actual working costs have not yet fallen in any substantial manner, but it is fairly clear that the maximum has been reached, and that an appreciable if small fall may be expected before long. As regards cost of supplies, there is at present few signs of reductions ; in fact, the price of dynamite has been raised.

As the new refinery for Rand gold approaches completion, the question is once more discussed of marketing the gold through a local selling organization, instead of sending it to Rothschilds in London. A suggestion has even been made that the output should be sold ahead on contract, thus helping to stabilize the market. We are not sure that this would have the effect desired. The selling of gold to advantage is an intricate and specialized business and requires close touch with all the banking centres of the world.

Rhodesia.—The output of gold during July was reported at 51,564 oz., as compared with 49,466 oz. in June, and 46,208 oz. in July of last year. Returns for July relating to other metals and minerals produced in Southern Rhodesia were : Silver, 12,620 oz. ; coal, 53,967 tons ; chrome ore 730 tons ; copper, 239 tons ; asbestos, 1,775 tons ; arsenic, 7 tons ; mica, 8 tons ; tin concentrates, 1 ton ; diamonds, 22 carats.

At the Lonely Reef, the development of the 24th level is now giving better results than at first. On the north drive, for 60 ft. from 100 ft. to 160 ft. the assay-value averaged $3\frac{1}{2}$ oz. per ton over 40 in. At 165 ft. the value was $6\frac{1}{4}$ oz. over 55 in. ; at 170 ft., $6\frac{3}{4}$ oz. over 51 in., and at 175 ft., $4\frac{3}{4}$ oz. over 64 in.

The admission of Southern Rhodesia to the Union of South Africa is once more being actively discussed by those in authority, although the popular vote last year was overwhelmingly against such a step. The change of view has followed on General Smuts' sweeping victory in the Union election. This victory is taken as a sign that the inhabitants of South Africa are now following a man who can think imperially and at the same time unselfishly. Louis Botha was a man of the same character, but did not have the extensive support of the Dutch citizens as Smuts now has. It is probable that under the new conditions Rhodesia may join the Union.

Some particulars are given under the heading "Geological Investigations in Rhodesia," in the Mining Digest this month, of the chrome deposits, recently discovered, which have already had such an effect on the market for this mineral. The article also gives some information relating to mica and graphite deposits.

West Africa.—The first return of the Goldfields of Eastern Akkim gave 85 oz. from 4,000 cubic yards. This was effected by a trial run of the new sluicing plant. At the par value of gold the yield was at the rate of 20d. per yard. Investigations are now in hand relative to the working of the ground by dredges.

Nigeria.—As will be seen from the report quoted elsewhere in this issue, the Ropp Tin company was not able to make a profit during 1920, in spite of its large output of tin concentrate, 1,017 tons. During the current year, the costs have been substantially reduced, and the company is now able to make a profit when the price of the metal is above £150 per ton. Mr. Edmund Davis, the chairman, believes that the price of tin will considerably improve after the end of the year, and he is not disposed to suspend operations in the meantime, as such a policy would entail expenses while working is stopped, and also in the subsequent reopening. The company's proved ground is estimated to contain about 10,000 tons of cassiterite.

Australia.—Further information has been given by the British Government with regard to the Australian zinc concentrates purchased. The total quantity held on March 31 of this year was 573,685 tons, while 11,943 tons was

delivered in April, 14,085 tons in May, 16,677 tons in June, 17,758 tons in July, and 22,418 tons in August. It is admitted that there is no prospect at present of disposing of the stocks at prices equivalent to the original purchase cost.

Cable advices give the results achieved by the Broken Hill Proprietary during the year ended May 31 last. The lead-zinc-silver mine was reopened on November 10, after the cessation of the strike, but was closed early in January owing to the unsatisfactory state of the metal markets. During the time of operation 3,875 tons of ore was raised, from which 801 tons of lead concentrate was obtained. The zinc plant gave 2,918 tons of zinc concentrate, the regrinding plant 557 tons of lead concentrate, and the slime flotation plant 1,487 tons of lead concentrate and 4,258 tons of zinc concentrate. At the iron and steel works the output of pig iron was 226,760 tons, and the open-hearth furnaces produced 209,458 tons of steel. A third blast-furnace was blown-in last month.

Alluvial gold has been found on Block 41, owned by Hampton Gold Mining Areas, Ltd., the reconstruction of Hampton Uruguay, Ltd. This is situated farther to the north-east of Hampton Plains than the Celebration and other discoveries of two years ago. It is close to the Trans-continental railway, at about 37 miles from Kalgoorlie. Mr. H. J. Daly, the manager, reports that the find is encouraging, though it does not justify a rush. The district has been proclaimed as a new goldfield, which is officially given the name " Transfind."

Malaya.—The arrangement between the Federated Malay States and the Dutch East Indies with regard to the sale of stocks of tin is to be continued. In February last it was agreed that neither should sell its stocks, purchased in the interest of the local industry, for a period of three months. In May the period was extended by another three months ending August 31. The present renewal of the agreement does not mention any date limit, so apparently the respective Governments do not expect any immediate chance for disposing of their stocks without further upsetting the tin market.

Cornwall.—The directors of East Pool have issued a circular relating to the policy which has become necessary since the collapse of the main shaft. As a matter of fact it is not a new policy, and the accident only had the effect of hastening the proposed modification in the method of attacking the ore. The circular reminds shareholders of the announcement made at the last general meeting that rich ore had been developed on both the Great lode and the Rogers lode, in the Agar section, in the direction of Tolgus, and that the sinking of a new shaft had become necessary. The fall of ground in May occurred over an extensive area in the old workings at East Pool. Although this fall affected the East Pool shaft at the 130 fm. level, and put out of action the electric pumps at the 80 fm., 180 fm., and 240 fm. levels, it was hoped then that the shaft could be repaired. However, continual further falls took place all through the month of June, completely wrecking the shaft and depriving the mine of its winding facilities. During July dams were completed in the cross-cuts to the Rogers lode, in order to isolate that lode in the Agar section from the old workings in East Pool, and salvage operations took place to remove the electric pumps and other material. There was then no alternative but to stop pumping and definitely abandon the old workings at East Pool, as the amount of water was greater than could be dealt with by the Cornish pump, and practically all the ore had been already worked out in this section. The directors have now decided that the new shaft referred to at the general meeting shall be at once taken in hand, and the position of the shaft has been definitely fixed at a point north of the present Agar shaft, where it will cut the Rogers lode at a vertical depth of about 250 fathoms. This shaft will be a combined winding and pumping shaft, and its position will enable it to be used for working the whole of the rich unexhausted portions of the Rogers lode to the west, and the undeveloped portions of that lode to the east in the direction of Tolgus, and also the rich lodes proved by bore-holes parallel to the Rogers lode. The directors say nothing about any arrangement with South Crofty with regard to the underground water question. The point is that when the East Pool pumps are out of action the clearing of the water falls entirely on the South Crofty pumps, which are not equal to the duty. If the newer part of the East Pool company's property is sealed off from the old property, South Crofty will never in the future receive any assistance from the East Pool pumps. There seems to be no alternative for South Crofty but to provide additional pumps.

Canada.—Our Toronto correspondent refers to the prosperity now being enjoyed by the Porcupine gold mines. At the McIntyre, an ore-body 30 ft. wide and assaying $20 per ton is being developed at the 1,375 ft. level, and the mill is to be extended so as to bring the capacity from 500 to 1,000 tons per day. A. Mitchelson and Co., Ltd., of London, has acquired a controlling interest in the Davidson Consolidated, north-east of Porcupine.

United States.—The position of the zinc industry is reflected in the figures of production and export during the first half of 1921. There was produced 100,781 tons from home ores and 1,744 tons from imported ores, making a total of 102,525 tons. These figures compare with 205,269 tons during the second half of 1920, and 258,108 tons during the first half. The stock at June 30 was reported at 94,747 tons, as compared with 71,037 tons at December 31, and 29,892 tons at June 30, 1920. The exports during the first half of 1921 were 2,255 tons, and the imports 7,405 tons. The imports are as a rule nothing at all, while during the immediately preceding half-years the exports were, respectively, 24,500 tons, 99,750 tons, 68,600 tons, and 77,600 tons. The figures here quoted indicate the present demoralization of the United States zinc industry.

Interest in the shares of the Arizona Copper Company has been revived by the statement that the deal with the Phelps-Dodge Corporation is at last nearing completion. In America the purchase of the properties by the corporation is generally accepted as an actual fact, and that only details of price are wanting to complete the transaction. It is presumed that the railway controlled by the Arizona Company will become part of the El Paso and South-Western system, and that the lighting and power service will be transferred to the Phelps-Dodge power house at Morenci, where Diesel engines give cheaper generation of current. It is stated that Mr. J. P. Hodgson, formerly manager of the Detroit Copper Co., is to be appointed manager of the Arizona Company's property.

The Alaska Gastineau Company, operating the Perseverance gold mine behind Juneau, has finally decided to suspend operations. In a lengthy article published in May, 1918, we reviewed the unfortunate position of this and of the Alaska Juneau company, which works a mine on the same line of lode. The Gastineau was controlled by the Jackling group, and the Juneau was an appanage of the Alaska Treadwell group. Both companies suffered owing to the low-grade ores proving far poorer than was estimated, while at the Juneau the milling plant, which was built to a new design, was not successful in practice. The cost of treatment turned out eventually to be much higher than was estimated, but this fact was, of course, beyond the control of those responsible. At the Gastineau it was originally estimated that 21,000,000 tons of proved ore averaged $1·75 in gold per ton, while the probable and partly developed ore was estimated at 75,000,000 tons, averaging $1·50. The operating cost was put at 75 cents per ton and the loss in tailing 25 cents per ton. Almost at once it was found that the average content had been over-estimated, for the first year's results showed an average assay-value of $1·15 per ton and an extraction of 93 cents. At first the cost was 69 cents per ton, but as harder ores were milled the cost of mining and treatment became greater, and at the same time war conditions sent up the cost of labour and supplies. As recorded last year, the position eventually became impossible, so that the recent decision to close down was not unexpected. During the time the mill was at work 11,711,314 tons yielded gold worth $9,508,168.

Mexico.—The Mexican Minister of Finance has made a compromise with the representatives of the United States oil interests, and his action has been approved by President Obregon. The result is that operations have once more been resumed, and the export tax has been withdrawn. The exact terms of the agreement have not yet been made known.

Russia.—The visit of Mr. Leslie Urquhart to Moscow is an important event, and hopes are high that he will be able to make some arrangement whereby the mines of the Russo-Asiatic Consolidated can be reopened. He leaves on his return on the 13th.

China.—The Eastern Pioneer Company, which has done so much good work in prospecting in Sze-chuan under the control of Mr. Pritchard Morgan and by the mining advice of Mr. H. W. L. Way, is being amalgamated with the Yang-tse Corporation, and additional capital is to be raised. It will be remembered that Mr. Way gave an account of the potentialities of this district in the MAGAZINE for July, 1916.

TRINIDAD:
A REVIEW OF ITS GEOLOGY AND OIL RESOURCES

By HENRY B. MILNER, M.A., D.I.C., F.G.S.
Lecturer in Oil Technology, Royal School of Mines

In the following article the author summarizes our present knowledge of the geology of the Island of Trinidad, with special reference to the mode of occurrence and storage of its oil. An account is given of the progress of development of the petroleum resources, and some of the more important technical difficulties encountered during oil exploration in the Island are discussed.

Introduction.

At the request of the Editor of The Mining Magazine, and also in response to the repeated suggestion from several sources, I have endeavoured in the following paper to present a concise account of the pure and economic geology of Trinidad, an account summarizing more especially our scattered knowledge of the important oil-fields extant in the island.

For its size, Trinidad possesses a really undue share of geological and structural complexity, and as is well known, controversial tectonic questions and stratigraphical problems make up no insignificant part of this somewhat striking feature. Notwithstanding the great amount of prospecting carried out in the past, it is surprising how little is really known of the geology of this island, and although it may appear paradoxical, the more geologists who visit the colony, the less we seem ultimately to know about it; this is a natural outcome of the tendency, both past and present, towards the elucidation of local geological features often without possible regard for the wider potentialities of the work; such localization is the unfortunate concomitant of oil-finding where private and not national interests are the first consideration, and in itself, of course, in no way reflects on the standard of the work carried out hitherto. Scientifically we may deplore the traditional lack of cohesion between geologists who serve solely the interests of different and possibly rival oil companies, and though we may agree strongly with Professor P. Carmody in advocating "team work" in the field as conducive to the best economic results for all concerned,[1] the fact still remains that most oilfield investigation is regarded primarily in the light of a confidential inquiry, whose evidence is stored up in the secret archives of the company responsible for its inception. This practice, while probably necessary in certain cases, obviously inhibits the grasp of the facts by a larger public, and it further retards, through lack of publication, the progress of geological knowledge of the island, a factor which is bound to be detrimental to the best economic development of its natural resources in the long run.

It is not surprising to find, therefore, that Trinidad only has a scattered and incomprehensive geological literature compared with many other oil-producing colonies, and in view of the very general interest evinced in the island at the present time, some coherent account of its geology and oil technology may not be out of place.

Physiography.

Trinidad lies just off the north-east coast of South America, from which it is separated by the Gulf of Paria, the distance measured from mainland to island (across the Dragon's Mouth) being about 12 miles. Both physically and structurally it is related to the South American continent, more particularly to northern Venezuela, whose tectonics are referable to those of the sunken Antillean continent now beneath the Caribbean Sea.[2] Trinidad forms the southernmost peak of a submerged mountain chain now represented by such islands as Antigua, Barbados, and Tobago, the chain constituting the middle Caribbean zone of folded sediments, as defined by Suess.[3] The trend of this chain is parabolic, with concavity facing west, and the island itself marks the turning point of the southerly limb of the curve as it swings round from N.E.-S.W. (Tobago) to E.W., the dominant strike of the Northern Range of Trinidad and of the Caribbean Hills of Venezuela.

Roughly quadrangular in outline, though breached by the sea, particularly on the west coast, Trinidad has a total area of some 1,750 square miles, and a coastline of 220 miles long. Geographically it presents

[1] "Trinidad as a Key to the Origin of Petroleum" Inst. Pet. Tech., May 10, 1921.

five well differentiated elements: (*a*) the Northern Range, (*b*) the "Swamp" area, forming the basins of the Caroni and Oropuche rivers, (*c*) the Central Range, (*d*) the Naparima Plain, and (*e*) the Southern Hills. The geological significance of these features will be apparent ultimately; for the present we may briefly note the physical characteristics of each.

(*a*) The Northern Range consists chiefly of two well-defined ridges, a foothill ridge with an average height of 800 ft., bordering the north coast, and an inland ridge rising to a height of 3,000 ft. in places. Both ridges stretch almost continuously from west to east coasts, having a total length of 53 miles. The range is tectonically connected with the Caribbean Hills of north Venezuela, of which it is but an eastward extension, the islands of Chacachare, Huevos, Monos, etc., constituting the intermediate links.

(*b*) The "Swamp" area is a typical savanna feature, reminiscent of similar though much more extensive river basins of the northern part of South America; it is formed by the drainage of the Oropuche river flowing east, and by that of the Caroni flowing west; a low watershed separating the two basins rises to a height of 220 ft., and is part of a sinuous divide, traceable at intervals across the island from north to south.

(*c*) The Central Range is composed of a series of comparatively low ridges stretching somewhat irregularly from Point-à-pierre on the west to Cocos Bay (south of the El Branche river) on the east; the average height of the range is about 850 ft., but it includes such hills as Montserrat, Tamana, and Mount Harris, all over 900 ft. high. The ridges are not continuous across the island, but are intercepted by valleys and ravines in which there is an abundant growth of tropical vegetation; the higher elevations are commonly well wooded, particularly in the west. A peculiar feature is the radial development of small ridges from Montserrat itself, five of which strike obliquely to the general E.-W. trend of the range, occasioning much irregularity of topography, characteristic of the western area.

(*d*) The Naparima Plain defines the region between the Central Range and the Southern Hills, and has an average breadth of 18 miles. Its character is that of a gently undulating plateau, occasionally broken by steep-sided valleys and monadnocks such as Naparima Hill and Dunmore Hill. Towards the east the plain becomes flatter as it approaches the swampy tract of the Nariva Lagoon.

(*e*) The Southern Hills are much less clearly differentiated than the other ranges to the north, and are not so conspicuously continuous across the island. One ridge occurs to the east of the Moruga river, stretching from Grandecaille Point to the Moruga valley; west of that valley the country rises again in the form of a broad elevation trending in a westerly direction to Siparia. The principal summits occur in the east, the Three Sisters, for example, rising to heights of over 700 ft. In the west the elevations are slighter, being seldom more than 250 ft. above sea-level. Mainly on account of the arenaceous character of the rocks involved, the hill slopes are often remarkably steep, especially in the eastern part of the range.

From the map (Fig. 1) it will be seen that the main drainage of the island is towards the east and west coasts, the principal watersheds being those of the Caroni, Oropuche, and Ortoire rivers; a portion of this drainage, however, finds its way into swamps such as the Oropuche and Nariva Lagoons, which are low-lying tracts of country bordering the west and east coasts respectively.

The climate is tropical, with a wet season from June to December, when the swamp areas are often quite inaccessible and the rivers impassable. The tropical heat, however, is frequently ameliorated by the prevalent trade winds, and where the principal hill ranges occur the conditions, even in the hottest and most humid months of the year, August and September, are not too trying.

On the lower slopes of the hills and in the plains, the soil is wonderfully fertile and the vegetation is accordingly luxuriant; much of this land is at present under cultivation.

The usual types of tropical fever prevail in the island, but the consensus of opinion shows that, with ordinary precautions, such risks can easily be minimized.

General Geology.

The original geological survey of Trinidad was instituted in 1855 by the Secretary of State for the Colonies, Sir William Molesworth, who was instrumental in

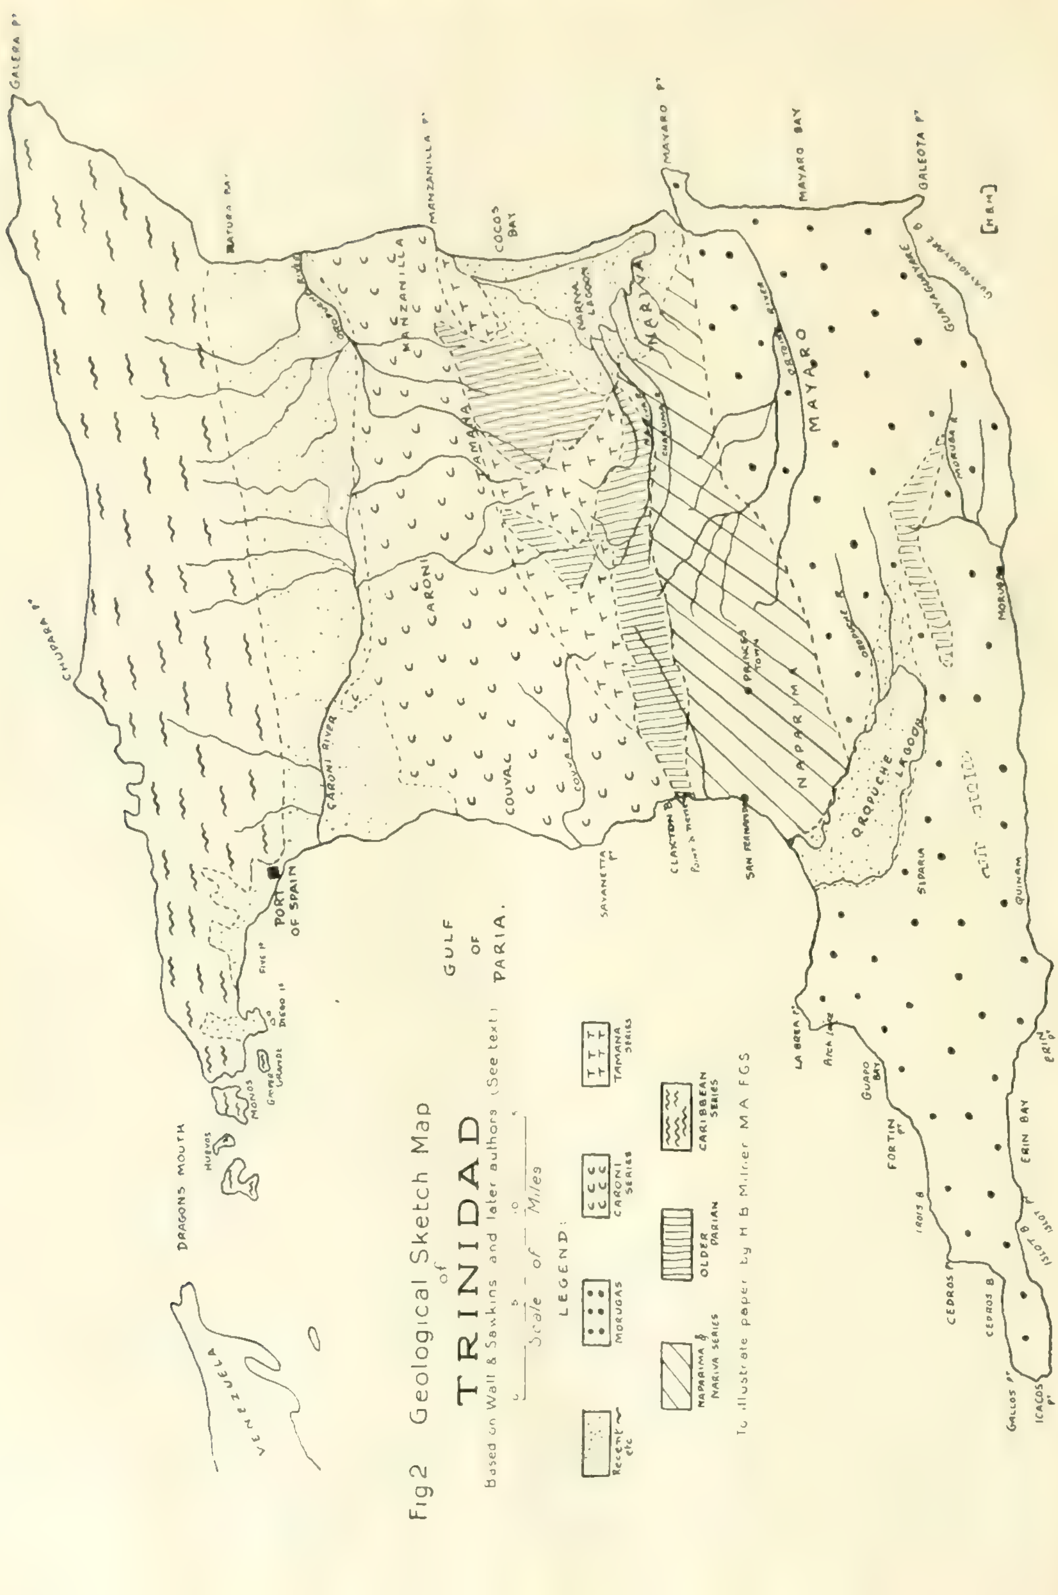

Fig 2 Geological Sketch Map of TRINIDAD

Based on Wall & Sawkins and later authors (See text)

To illustrate paper by H B Milner M A F G S

obtaining Treasury sanction for this and for the scientific investigation of other West Indian colonies. It was Murchison who had the task of selecting a suitable staff, and as director-general of the Geological Survey he appointed G. P. Wall as chief geologist, a former pupil of the Government School of Mines, at that time established in Jermyn Street. J. G. Sawkins, a fellow of the Geological Society and a man already known from his work in Mexico and Cuba, was also recommended by Murchison to accompany Wall, and in this way the classic survey of Trinidad by Wall and Sawkins came to be inaugurated. The work was actually carried out during the years 1857 to 1859, and in 1860 the "Report on the Geology of Trinidad"[4] was issued jointly by those geologists as a memoir of the Geological Survey. This memoir, now both long out of date and print, formed the basis of much of the subsequent economic work in the island, and although later researches have modified much of the geology therein described, the general principles enunciated by the authors still maintain a certain technical value.

Wall and Sawkins divided the rocks of the island into three well differentiated series corresponding approximately with the dominant physiographical elements described in the preceding section; the sequence they established was as follows:—

Tertiary.	3. Newer Parian Group[5]	*a.* Nariva Series. *b.* Naparima Marl. *c.* Tamana or Calcareous Series. *d.* Caroni or Carbonaceous Series. *e.* Moruga or Arenaceous Series.
Cretaceous.	2. Older Parian Group.	
(Metamorphic).	I. Caribbean Group.	

The broader divisions still hold within certain limits, the Caribbean group having its typical development in the Northern Range, the Older Parian group in the Central Range, and the Newer Parian group in the southern part of the island; recent work, however, has modified our ideas of the distribution of the Older and Newer Parian groups because in the Central Range, for example, rocks belonging to the Newer Parian group certainly occur. For purposes of description it is convenient to take this classification as a basis, reserving for future discussion such alterations rendered necessary by subsequent detailed work.

(1) The Caribbean Group.—This group comprises a large and heterogeneous series of rock types in which mica schists, quartz schists, crystalline limestones, and foliated quartz and felspar rocks occur together with less deformed sandstones, shales, quartzites, and conglomerates; these rocks have for the most part suffered intense folding and shearing, and the metamorphism produced varies in character, being greater in the western than in the eastern part of the island. Dalton[6] has shown that the series is typically developed on the mainland in the Caribbean Hills of Venezuela; the crystalline limestones of eastern Venezuela correspond lithologically to the similar facies occurring in western Trinidad (Levantille Hills), and the mica schists and graphitic schists of the former country are recapitulated in many of the highly foliated rocks of the north-west coast of the island. The connecting islands of Chacachacare, Huevos, and Monos, between Trinidad and the mainland, are also composed of rocks of this series, and they represent partially submerged summits of the mountain mass forming the southern border of the ancient "Antillean Continent," remnants of which are now extant in the Caribbean Hills of Venezuela and the Northern Range of Trinidad.

With regard to the geologic age of this group, considerable difference of opinion prevails. Wall and Sawkins are discreetly reticent on this point, though they suggest a "remote" origin; Ells[7] remarks on their lithological resemblance to Huronian or possibly Lower Cambrian rocks in Canada, but the subsequent discovery of some rather doubtful fossils (alleged to be *murchisonia* and *favosites*) in the limestone of the Levantille Hills is certainly suggestive of a Palæozoic age, a point receiving some support from Dalton, who assigned the Caribbean series of the mainland to at least early Mesozoic, Palæozoic, and possibly

[4] For Her Majesty's Stationery Office: published by Longman, Green, Longman, and Roberts. 1860.

[5] Subdivisions of this group *not* arranged in stratigraphic order.

[6] L. V. Dalton, *Geol. Mag.*, 1912, pp. 203–10 and references.

[7] R. W. Ells, Trans. Roy. Soc. Canada, 1907, section iv, p. 117.

Archæan epochs. The latest view is that of Cunningham Craig, who regards the group as Jurassic (not older) or possibly merely altered Cretaceous.[8] It would seem, however, that the balance of opinion at the present time favours a Palæozoic age, though doubtless younger rocks are represented as in Venezuela.

The thickness of the group is another unknown factor, though Wall and Sawkins' estimate of 10,000 to 12,000 ft. is probably highly exaggerated; folding on such an extensive scale as has operated here is bound to produce much faulting and repetition of beds, and Cunningham Craig's computation of the real thickness as being not more than 2,000 ft. is probably far more correct.

(2) Older Parian Group.—As originally described, this group embraces a series of sandstones, clays, carbonaceous shales, and limestones, and also a peculiar deposit known as "argiline,"[9] a siliceo-calcareous claystone, typically developed at San Fernando Hill. The coast section at Point-à-Pierre exposes several facies of this series, and the dark-grey clays and shales with their ferruginous concretionary bands give rise to a very distinctive reddish soil, traceable for some distance inland. The group as a whole is characteristic of the Central Range of the island, extending from the east to the west coasts; it also forms the cores of several hills in the Naparima area such as the Mont Chagrin, Dunmore, and San Fernando Hills, and outcrops in several places from beneath the Tertiary deposits along an elongated tract of country bordering the south coast.

In many instances the rocks show the result of extreme folding, which took place prior to Tertiary deposition. Fossils are peculiarly scarce and the evidence as to geological age is based on lithological similarity to beds at Cumana, Venezuela, which contain definite Neocomian species. Recent work has shown that these deposits in Trinidad may be in part Tertiary, but their accurate delineation both as regards stratigraphical age and geographical distribution can only be settled by very careful detailed survey. This question of age has an important bearing on the geology and prospects of the Tabaquite and Piparo oilfields.

[8] E. H. Cunningham Craig, Geol. Structure of Trinidad, Victoria Inst. of Trinidad and Tobago, 1905.

[9] The argiline is now regarded by some workers as being of Tertiary age.

(3) Newer Parian Group.—The subdivisions of this group quoted above are based on lithological differences, and do not represent successive stratigraphical horizons; the differentiation of the rocks in the field has presented problems of the greatest complexity owing to their heterogeneous characters and varying developments. An explanation of the occurrence of the several facies of Tertiary deposition (and more have been recognized since Wall and Sawkins originally described the group) is to be found in extensive lateral variation, consequent on the existence of different physical conditions under which they were deposited; the sediments were laid down on a (presumably) Cretaceous land surface, in most cases unconformably, and with marked overlap; as a result of the differential erosion of that land, and also as a result of collateral earth movement with sedimentation, deep water, shallow water, and estuarine deposits were formed contemporaneously, and thus a variety of rock types were evolved.

These beds occur on both sides of the Central Range, though their maximum and most important development is in the southern third of the island. The Tamana and Caroni series are typical of the northern region, and the Nariva, Naparima, and Moruga series of the southern region. It is the geological range of the individual series and their correlation, even over comparatively small areas, which have constituted the chief analytical problems in the field, and as these rocks contain the main oil-producing beds at present known in the island, their correct interpretation is a matter of supreme economic importance.

(*a*) *The Nariva Series.*—As originally defined, this series consists of clays, shales, and occasional limestones, yielding a characteristic reddish soil; the rocks are traceable from the west (Naparima) to the east (Nariva) at intervals, but their relations to the Older Parian series are obscure. In the western area the Nariva series is represented by the San Fernando sandstone series, consisting of sandstones, clays, and silicified marble; they are here overlain by the Naparima Marls.

(*b*) *Naparima Marl.*—Typically developed in the Naparima plain and presenting at least three well-marked facies, an older marlstone series resembling massive chalk and including intercalations of clay and foraminiferal sands, a later nodular

calcareous sand, massive and unbedded, containing *globigerina*, *nummulina*, and other foraminifera, and an uppermost green clay; these facies have been chiefly recognized in the western area. This marl series is succeeded by a thick series of clays, the Naparima or Globigerina Clay, consisting of buff-green and bluish-green clays with a glauconitic sandstone at base and top. In age the Naparima marls probably range from late Eocene to early Miocene, the overlaying clay series being regarded as Miocene.

(*c*) *Tamana or Calcareous Series*.—Wall and Sawkins include under this heading the massive limestones of Tamana and Montserrat, with their associated sands and shales, developed on the northern side of the Central Range and alleged to be unconformable to the Older Parian wherever they occur. Guppy has described their lithological and palæontological characteristics,[10] and has shown that the limestones contain several new species of Tertiary mollusca. These limestones seem to form the base of the series and they are overlain by sands, shales, and conglomerates of estuarine origin.

(*d*) *Caroni or Carbonaceous Series*.—This series was originally differentiated as typified by the rocks exposed in the coast section between Manzanilla and Oropuche on the eastern border of the island. Wall and Sawkins recognized a lower non-carbonaceous division consisting of shales, clays, and sands, and an upper carbonaceous series of sands, shales, and coal seams, chiefly met with on the western coast. The geological age of the series is doubtful, Dall regarding them as Oligocene,[11] and subsequent workers as Mio-Pliocene.[12]

(*e*) *The Moruga Series*.—Extensively developed in the southern part of the island, from the south coast to the Ortoire valley. On the whole these rocks have decided estuarine characters and consist chiefly of loose sands, calcareous sandstones, and carbonaceous shales ("lignite seams") as at Point Moruga. At Erin on the south coast the series includes a peculiar "porcellanite," an indurated shale owing its origin, according to Wall and Sawkins, to the (? spontaneous) combustion of associated carbonaceous matter;[13] this rock also occurs at Point Cedros, Point Rouge, and locally at Moruga. The Moruga series is now very generally regarded as being of Pliocene age.

Practically the greater part of the existing divergence of opinion as to the Tertiary stratigraphy of the island is centred in the recognition and correlation of the various members of the Newer Parian group; in the space here available it is impossible to do more than mention one or two of the recent theories, but it may be remarked at once that in the opinion of most workers in the island our knowledge is still insufficient to permit of any dogmatic assertions as to the relative ages and distribution of the beds.

Cunningham Craig regards the Moruga series (as defined by Wall and Sawkins for the southern part of the island) as equivalent to the whole of the Tertiary sequence developed elsewhere, and the Tamana and Caroni series he regards as corresponding to the lower and upper divisions of the Morugas respectively.[14] Again, in the southern area, two distinctive groups of oil-sand have been recognized as the Lower and Upper Galeota groups; their precise horizons have been doubtful, but the same author considers them as being of lower Tertiary age and as representing the lower part of the Morugas. Cunningham Craig's middle Tertiary embraces the middle Moruga series, which includes the Naparima clay and marl series, of Oligocene age according to Dall,[15] but of Miocene age according to the first writer.[16] The typical Moruga sands, lignites, and porcellanites, together with the La Brea oil-sand, constitute the uppermost horizons of the Moruga series, and are assigned by Craig to a late Miocene or early Pliocene age.

Again, during the course of oilfield development, a great many local names have come into existence designating certain sands or particular horizons of economic importance in the Tertiary series. In this connexion mention may be made of the "Morne L'enfer sandstone," "Forest Clay,"

"Forest Sand," and the "Cruse sands"; the first three are typically developed in the Fyzabad and Point Fortin fields, the Morne L'enfer sandstone overlying the Forest Clay which includes the productive Forest Sand, the two latter equivalent to the Naparima series (in part). The Cruse sand is a local development of the lower Tertiary series principally in the south-eastern part of the island, and is possibly the equivalent of the so-called Lizard series of the south-western peninsula.

More recently still, the palæontology of these Tertiary beds has received considerable attention at the hands of Douvillé,[17] Penny, and others ; the work has been largely a study of the foraminifera occurring in the Naparima series, on account of the great economic importance of that series as the chief oil-producing horizon. It would seem, however, that despite this detailed work, correlation of the beds is still far from satisfactory, and more than one doubt has been expressed as to the ultimate stratigraphic and economic value of the results. So many species occurring in these rocks have unfortunately a long range in time and wide distribution in space, and consequently are of little value as indices of any but the broadest divisions of geologic time ; nevertheless, there is no reason why more detailed palæontological work of this description should not yield important criteria, especially if, as our knowledge increases, certain species can be segregated for purposes of precise zoning.

A method of attack in problems of correlation of the sediments over small areas has been successfully employed by V. C. Illing during the course of his work in Trinidad ; [18] the method is based on an intensive study of the petrography of the deposits, and the results have hitherto been most encouraging. Much more attention is now being paid to this hitherto neglected branch of petrology, and in thus bringing new light to bear on the peculiarly complex problems of stratigraphical correlation in the island, it is to be hoped that far-reaching scientific and economic results will eventuate.

Tectonics.

Although some little account of the tectonics of the main groups into which Wall and Sawkins divided the strata of Trinidad appears in their memoir, the information given is exceedingly scanty, and we owe the first real attempt at the elucidation of the structural features of the island to Cunningham Craig, whose work has been published in various Council Papers (Trinidad) and elsewhere.[19]

From the economic standpoint the most important geological structures occur in the southern part of the island, and it is this region which has naturally received the more detailed attention in recent years ; with the development of the Tabaquite oilfield, the Central Range structures have claimed more careful attention, and a great deal of work has been carried out to this end, though little has been made public. The northern area is commercially unattractive, and the structural features are on that account little known except in broad outline.

Reviewing the facts in the light of present knowledge, however, we can recognize in Trinidad at least three dominant phases of earth-movement operative, as far as can be ascertained, in pre-Cretaceous, late Cretaceous, and Tertiary times respectively. The pre-Cretaceous folding involved the rocks now forming the Caribbean Hills of the mainland and the Northern Range of Trinidad ; the evidence shows that this folding was produced by horizontal earth stress acting along a N.N.W.-S.S.E. line, and the production of a series of parallel folds, disposed en echelon, has impressed an E.N.E.-W.S.W. strike on the rocks which gives the dominant character to the physical relief of Northern Venezuela and Trinidad. In the Northern Range there is noticed a strong tendency to the development of "fan-structure" with concomitant faulting and thrusting ; the latter elements have played but a subordinate part in the evolution of the present structures, the marked repetition of strata being a function of folding rather than of dislocation in this case.

The Cretaceous folding affected principally the sediments of the same age, and to this phase of earth-movement we can assign the initiation of the Central Range. It is probable that the movement actually took place collaterally with sedimentation, and there is evidence also that the basin of deposition received a slight tilt in a N.W.-

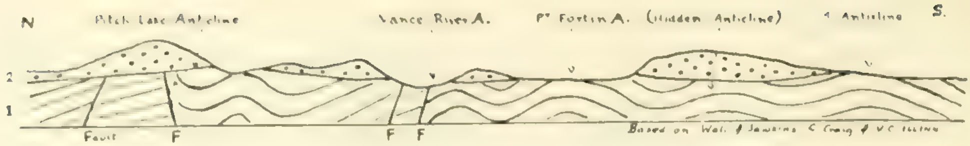

Fig 3 DIAGRAMMATIC SECTION FROM NORTH TO SOUTH ACROSS MAIN ANTICLINAL FEATURES

[1 - Naparima Series. 2 - Moruga Series]

S.E. direction, with elevation towards the S.E. As deposition advanced, the earth movements continued to gather in intensity, and they culminated with the formation of a series of N.E.-S.W. folds, recognizable in the Central Range, and also in the Cretaceous rocks of the mainland. On the whole the degree of flexuring was not so great as in the case of the northern metamorphics, but it was quite sufficient to produce the sharp asymmetrical fold features characteristic of the Older Parian rocks.

Tertiary folding also took place at the time of deposition, reaching its maximum phase towards the close of Miocene times; the early and middle Tertiary deposits were laid down on the eroded Cretaceous land-surface, the sediments becoming involved in flexuring along E.-W. axes, consequent on earth-movement from the south. In this way the Cretaceous N.E.-S.W. folds became modified in the southern part of the island, much as the Caledonian folds are truncated by Miocene uplifts in southern England, and in Trinidad, as in Venezuela and elsewhere, the effect of such tectonic interference was to produce quaquaversal structures, often quite local, but of importance from the point of view of oil accumulation.

Cunningham Craig has shown that the main result of this Tertiary folding was the formation of a well-marked series of anticlines and synclines,[20] in three cases extending right across the island. It is these structural elements with which are associated the principal oilfields of the island, and they may be differentiated as follows (see map, Fig. 5):—

(*a*) The Southern anticline, traceable from Galeota Point to the south-western promontory of the island, in a direction approximately parallel to and bordering the southern coast.

(*b*) The Point Fortin anticline, traceable from Mayaro Bay, along the southern side of Rock River and north of Siparia to Point Fortin.

(*c*) The Vance River anticline, starting from a little north of Mayaro Point and traceable across the basin of the Ortoire River and its tributaries, through the Oropuche Lagoon to Guapo Bay.

(*d*) The Pitch Lake anticline, occurring at La Brea Point and extending eastward along the southern main road.

(*e*) The San Fernando anticline, of doubtful extent, and

(*f*) The Central Range anticline, a less clearly defined feature in the central part of the island.

An intermediate line of flexure occurs between the Point Fortin and Southern anticlines, lying midway between Erin Point and Siparia; although for the most part hidden, it is quite possible that its linear extent may be considerable.

Besides the above-mentioned folds, a great many local and subordinate flexures occur, particularly in the southern part of the island; their individual characteristics are but little known except to company geologists, though in general their relations to the larger tectonic features are evident. The diagrammatic section, Fig. 3, illustrates some of the most important folds.

(*To be concluded.*)

The Iron and Steel Institute held its autumn meeting in Paris during the week beginning September 5. In addition to the usual sessions at which technical papers were read and discussed, a number of excursions were arranged. One of these excursions covered the Lorraine iron ore fields; a second consisted of a visit to the steel works of Creusot and Chamand; while a third was to the iron deposits and industries of Normandy. A reception was given by the Comité des Forges on September 5.

THE VENTILATION OF DEAD-ENDS IN MINES

By STANLEY NETTLETON, M.Inst.M.E., Assoc.Inst.M.M.

THE desirability of completing the development work of a mine as soon as possible after its inception renders the problem of efficient ventilation a matter of great importance to mining engineers. In addition to the primary consideration of safety of the workmen, the relationship between time and costs must not be lost sight of, for a sinking shaft or heading is generally of no value until completion. The interest on capital expended may amount to a considerable sum.

Blasting operations in "dead-ends" may take place several times daily, and it is desirable that workmen on each occasion should return to the face as quickly as possible consistent with safety.

In metalliferous mining it is a common practice immediately before firing a charge of explosives to open taps on the compressed-air service in the immediate vicinity. This certainly results in the introduction of cool and pure air into the working face, but the disadvantages of this method of ventilation are obvious. Even when a water-blast is employed the discharge of air at high pressure tends to place dust in suspension in the atmosphere, and the cost of removing blasting fumes efficiently may be excessive, as from a pipe 1 in. in diameter there may be discharged 15,000 to 20,000 cubic feet of air per minute.

A working face is frequently well ventilated by the exhaust of machines during drilling operations, but these only occupy a portion of the time when men are engaged in the shaft or drive. In order to maintain the efficiency of labour it is essential that fresh air should be provided in large volumes for dilution of noxious gases and reduction of temperature.

Among the arrangements which have been extensively adopted for the conveyance of fresh air to the faces of dead ends are pipes of large sectional area, and the division of the shaft or roadway into two portions by means of a partition of canvas or other material fixed from floor to roof in a line parallel to the heading. The difficulties associated with the fixing and maintenance of these devices are well known to men on the work. Air conduits of light metal or casings of wood are cumbersome and heavy. The cost of transport, erection, and dismantling on the completion of mine development may be greater than the initial cost of material employed. The removal of rigid air conduits is usually carried out in so hurried a manner that they require the attention of fitters or carpenters before they are fit for further use elsewhere.

With the greatest care in erection, the amount of leakage is apt to be excessive, particularly if the conduits are subject to vibration due to air-blasts arising from the use of explosives. The leakage of air is much greater than is generally realized by those in charge of the plant.

Tests made at the South Star Mine, Ballarat, Australia, showed that on forcing 3,830 cubic feet of air through 3,230 ft. of ventilating pipe 11 in. in diameter only 510 cu. ft., or 13 % was delivered at the face. At another mine in Victoria the relative quantities of air forced into the system and delivered where it was required were 4,630 and 1,136 cu. ft. per minute respectively, an efficiency of 24%. To obtain even moderate efficiency it is essential that with the metal or wooden air-conduits very great care must be taken in installation and maintenance to avoid leakage at joints. Rigid air conduits cannot be carried near a working face where explosives are used without risk of damage from falling rock, and when, as is frequently the case, box-holes have to be opened out on a drive in course of development the temporary removal of ventilation arrangements may be a matter of considerable inconvenience. Metal pipes or wooden boxes 1 or 2 ft. in diameter cannot be readily stored in a roadway where tramming operations are being carried on.

The division of a roadway into two sections for ventilation purposes has several disadvantages. Canvas sheeting extending from roof to floor does not make a very satisfactory joint even at the low ventilating pressures which exist in airways of large sectional area compared with totally enclosed conduits. When increased width of roadway is necessary extra cost is entailed in most instances. Though this may not be a serious matter when the road is entirely in coal or ore-body the question of roof support may demand serious attention. At some collieries in Lancashire these difficulties have been surmounted by building in the centre of the roadway a brick wall, which serves the double

purpose of supporting the girders, sustaining the roof and dividing the road into intake and return airways. This has proved to be an efficient though costly method of dealing with the problem. The erection has to be carefully carried out, and the cost, chiefly due to the amount of labour employed on the work, prevents this method of ventilation from being largely adopted. For general practice the most satisfactory arrangements for the supply of fresh air to dead-ends appear to consist of some form of conduit which has considerable sectional area, is simple in installation, and can be readily removed when necessary. Many attempts have been made to use collapsible canvas conduits designed to comply with the above requirements. In an Austrian device the conduits are rec-angular in section, the canvas being supported by a light frame of wood or metal. Owing to difficulties in manufacture at low cost and risk of leakage at joints which cannot be made satisfactorily when the main has not a regular alignment, this type of ventilating conduit has not been largely adopted. Canvas tubes of circular or oval section offer greater possibilities of success, but the connexion between the individual lengths presents difficulties. The use of half-flange joints coupled by bolts involves the use of a spanner in erection and removal, apart from the disadvantages of cost and weight. Owing to corrosion by acid mine water it may be necessary for the iron connexions to be cut apart, and further cost is entailed in labour for removal of bolts and clamps.

The use of the Ventwal patent joint appears to solve most of the above-mentioned problems. It consists of two oval rings, overlapped by the canvas which forms the air-conduit. The connexion is made by inserting one ring into the open end of another length of canvas. One end is then rotated 90°, so that the two rings are exactly parallel to each other when they are drawn together. The canvas surrounding the metal rings makes an air-tight joint, the efficiency of which is increased by any further tension upon it. Over eleven miles of these tubes have been sold to mining companies in England and abroad. They are made in lengths of 20 ft., and of any required diameter. Tubes of 36 in. in diameter have been supplied to a copper mine in Rhodesia, and five repeat orders were received from an English colliery company last year. They are light, and may be suspended from roof timbers or carried on plugs driven into the wall. The stiffness of the canvas employed prevents collapse, even when working on exhaust pressure, but as the tubes may be used on irregular drives or laid over broken ground, each length of 20 ft. contains four iron supporting rings.

To obtain a rot-proof canvas has been a matter of some difficulty, but the Telephos Co., Ltd., of Vaughan Road, West Harrow, Middlesex, the licensees for the manufacture of Ventwal tubes, have placed on the market tubes of canvas specially treated to render it resistant to the acid water and the deleterious fumes so frequently met with in mining work.

The forcing of air at high pressures through pipes is a most uneconomical and usually a very inefficient method of ventilation. Pressures equal to 20 to 30 inches water-gauge, produced by Roots blowers, have been recorded in details relative to the ventilation of shafts and headings in Australian mines.

Expenditure in installing larger air-pipes would be well justified by reduction in working costs and by improvement in air supply in these cases. The air current should be at as low a pressure as is possible consistent with efficiency of service, and though the use of blowers and fans driven by engines or motors has sundry advantages, a jet of air placed in a pipe of large section has much to recommend its application. It is simple and not likely to get out of order, and where the pressure is within reasonable limits it is remarkably efficient as an injector.

A few years ago tests were made by Mr. E. Pam on the Geldenhuis Deep gold mine, Johannesburg, on a 538 ft. length of 9 in. pipe with four right-angle bends, with the following results, the air pressure on the mains being 72 lb. per square inch :—

	Size of Nozzle.	Discharge in cubic feet per minute.	Theoretical from Tables. Free air per minute produced by jet.
	in.		
Flange on	$\frac{1}{16}$	210	5
	$\frac{1}{8}$	530	19
	$\frac{3}{16}$	770	43
	$\frac{1}{4}$	1,080	76
Blind flange on intake of pipe	$\frac{1}{4}$	80	Quantity of air actually measured coming out of nozzle.

These practical tests show that the consumption of air from the compressor service is from $\frac{1}{40}$ to $\frac{1}{14}$ of the total amount of fresh air forced through the ventilating pipe.

The use of air from the compressor engines as a source of supply, and not of power for ventilation cannot be too strongly condemned.

It is becoming generally recognized that ventilation is a factor of importance in dealing with mining costs, owing to its influence on the efficiency of the worker. Labour costs have increased enormously in recent years, and the miner who is supplied with an abundance of cool and pure air is more likely to do a fair day's work than those who toil in a warm atmosphere contaminated by traces of blasting fumes. Bad ventilation has far-reaching effects. Men not only become inefficient underground, but on reaching the surface in a condition described as "played out" they are ready to listen to any argument in favour of striking for higher rates of pay for work which in the opinion of their employers is costing much more than is reasonable.

With the exhaustion of the older mines,

SHOWING HOW VENTWAL TUBING CAN BE PUT THROUGH NARROW AND IRREGULAR FISSURES.

the question of ventilation becomes more important owing to increase of temperature with greater depth of working. It is in development work and in outlying parts of a mine that the ventilation is most likely to be unsatisfactory. In many mining areas these should receive more attention than appears to have been given to them in the past, when high wages and a short life underground were generally regarded as prominent features in the life of the miner. Apart from considerations of health and contentment of employees, which should be regarded as matters of first importance, the influence of good ventilation in the mine on working costs should never be overlooked.

CRUSHING AND CONCENTRATION AT MOUNT LYELL

In our issue of November last we quoted from a paper by Mr. L. V. Waterhouse, describing the flotation plant recently brought into use at Mount Lyell. Since then we have received some notes from the company, giving an outline of the crushing, sorting, and dressing plant, describing the course of the ore through the plant, with special note of the rearrangements introduced for the purpose of saving labour. It will be remembered that the ore from the Mount Lyell mine is pyritic, and low in copper and silica, while that from North Lyell is higher in copper and contains much silica. Some of the North Lyell ore can be picked and sent direct to the smelter, while the rest requires concentration. The ore from the Lyell Comstock all requires concentration.

The first-class North Lyell ore as it arrives from the mine is dumped into the bins reserved for it, as shown in the diagram herewith. From the bins the ore is fed over a grizzly, which screens out the material *minus* $1\frac{1}{2}$ in. in size. The *minus* $1\frac{1}{2}$ in. material falls through a chute on to No. 4 conveyor, which in turn discharges it on to the inclined conveyor No. 5. The latter carries the *minus* $1\frac{1}{2}$ in. material to the top of the mill, where it is distributed over the mill-feed bins by a conveyor.

The oversize, or material too large to pass through the $1\frac{1}{2}$ in. grizzly, falls upon No. 1 conveyor, and discharges over a chute on to a shaking grizzly-feeder, where it is washed and the material *minus* 4 in. screened out. The oversize from the shaking grizzly-feeder is fed into the jaws of No. 1 crusher, which crushes to 4 in. The *minus* 4 in. material from the shaking grizzly-feeder, together with the crushed oversize, falls upon the inclined conveyor No. 6. This raises the crushed and washed ore to the top of the sorting plant, and discharges it on to the sorting belt or conveyor No. 7. The ore on the sorting belt passes in front of the sorters, who pick out the lower-grade material, depositing it in chutes, which discharge on to No. 8 conveyor, and thence into the reject bin. The higher-grade ore is left on the sorting belt, and from there passes over conveyors Nos. 9 and 10 to the sorted ore-bin. From this bin the sorted ore is taken in trucks to the smelter bins.

The reject ore is fed from the reject bin by two reciprocating feeders on to the inclined conveyor No. 3, which serves as a belt feed to No. 3 crusher set to crush to $1\frac{1}{2}$ in. The $1\frac{1}{2}$ in. product from No. 3 crusher falls upon No. 4 conveyor, passes to No. 5 conveyor, and thence to the mill-feed bins, joining the *minus* $1\frac{1}{2}$ in. material already referred to.

The second-class North Lyell ore is delivered into bins as marked in the sketch, and is passed over grizzlies having $1\frac{1}{2}$ in. spaces. The *minus* $1\frac{1}{2}$ in. material falls on to No. 4 conveyor, thence to No. 5 conveyor, and on to the mill-feed bins, to join the $1\frac{1}{2}$ in. material noted above. The oversize falls on to No. 2 conveyor, which serves also as a belt-feed to No. 2 crusher, set to crush to 3 in. approximately. The 3 in. product from No. 2 crusher falls on to No. 3 conveyor, and thence to No. 3 crusher, where it is crushed to $1\frac{1}{2}$ in. The $1\frac{1}{2}$ in. product from No. 3 crusher travels over the same course as noted in the case of the reject ore.

The Comstock ore is delivered to the mill-feed bin, which also receives some of the second-class North Lyell ore. The ore passes over a $1\frac{1}{2}$ in. grizzly directly into the jaws on No. 4 crusher set to crush to $1\frac{1}{2}$ in. The $1\frac{1}{2}$ in. product from the crusher joins

the *minus* 1½ in. product from the grizzly, and is elevated to the distributing belt over the mill bins.

It will be seen from the foregoing that all the ore delivered to the sorting and crushing sections is, after removal of the higher-grade material, crushed to 1½ in. and sent to the mill-feed bins. The combined 1½ in. material is delivered, via two roll feeds and a short cross conveyor, on to a ½ in. shaking screen feeder. The oversize from the shaking screen is crushed and elevated, and returned to the screen, all material eventually having to pass through the screen. The *minus* ½ in. product from the screen is elevated to the feed of the Hancock jig, which makes three products, concentrates, middlings, and tails. The concentrates are lifted in an elevator to a dewatering vat, and from there are taken in trucks to the smelter bins. The middlings are crushed in a set of fine-crushing rolls, the product from the rolls joining the feed to the jig for re-treatment. The tailings are delivered to an elevator and lifted to a shaking screen-feeder having ⅛ in. holes.

The oversize from the screen-feeder is crushed through a set of fine rolls and returned to the screen via the elevator. The *minus* ⅛ in. material passing through the screen is elevated to a diaphragm cone, where the excess water overflows to two Dorr thickeners, and the sandy discharge is fed directly into two tube-mills. The ore, after being ground in the tube-mills, is discharged into the boot of an elevator and lifted to the feed end of a Dorr classifier. In the classifier all material that has been sufficiently crushed is separated from the coarser material, and overflows to the boot of the Minerals Separation feed-elevator. The sandy discharge from the classifier joins the discharge from the cone, and is returned to the tube-mill for further grinding. The thickened slime from the Dorr thickener joins the overflow from the Dorr classifier in the boot of the Minerals Separation feed elevator, and is lifted to the Minerals Separation machines for further treatment.

The ore, which has now been reduced to *minus* 65 mesh, is fed to the Minerals Separation boxes, of which there are twelve. The first eight boxes produce concentrates and tailings. The tailings from the first eight boxes are treated in the last four boxes, where a middling concentrate is produced which is returned to the first eight boxes for re-treatment. The tailings from the last four boxes then pass over a small cascade box, the float from which joins the middling concentrates from the last four boxes for re-treatment. The tailings from the cascade box are sent to the dump. The concentrates from the first twelve boxes are elevated to Oliver and Portland filters, where the excess water is removed, leaving a concentrate carrying from 11 to 15% water. The filtered concentrates fall upon a conveyor that delivers them into a bin, from which they are loaded, weighed, and sent to the smelter for further treatment in the Dwight & Lloyd sintering plant. After sintering the concentrates are combined, in proper proportion with the sorted ore, jig concentrates, Mount Lyell ore, and fluxes, and smelted in the blast-furnaces.

Sorting Plant at Mount Lyell.

LETTERS TO THE EDITOR

The Origin of Primary Ore Deposits

The Editor :

SIR—Mr. Kendall has had wide experience of ore deposits, and I appreciate the compliment of his contributing (in the MAGAZINE for May last) to the discussion of my paper on the origin of primary ore deposits. I regret, however, that his article contains so much evidence that he did not either grasp my views or study my paper adequately.

I made no attempt at "explaining the well-known features of the different classes of ore-bodies." I sought an explanation of how metals are segregated from their original disseminated condition in rock magmas, in what condition of solution they are carried in magmatic liquids, and the causes of their deposition as ore minerals therefrom.

For my purpose drawings were of no value whatever.

In connexion with crust formation and foundering and the differentiation of primeval magma, Mr. Kendall has missed what I say at the bottom of page 9 of my paper : "The crust became permanent long before the capacity of the fused silicates for the absorption of water and oxygen was satisfied, then general absorption was prevented and the molten mass no longer in violent agitation underwent segregation into an acidic portion above and a basic portion below"; also the first paragraph on page 10 : "The top of the crust was probably not truly granitic, but considerably more basic since it was only after its formation that the segregation upward of the acidic sub-magma could have taken place."

I have no means of access here to the records of the United States Geological Survey, and I am not conversant with the work of Barns referred to. Where the fallacy comes in I do not know, but it is obviously incorrect to assert that fragments of any solid can float on a liquid the density of which is less than that of the solid.

That an aqueous mother-liquor is given off by magmas, which, on consolidation, yield granite, is so widely accepted that it seems unreasonable to regard it as anything but a fact as well established as any such process can be. Mr. Kendall says I do not give the evidence on which the "assumption" is based. He has overlooked what appears in the middle of page 7 : "We come to this conclusion on the evidence of quartz and pegmatite veins, one or both of which are invariably found in or above granite batholiths. These veins are not filled with quartz or pegmatite in a state of simple fusion, and there is no doubt that the elements of water were present in the liquid from which they were derived."

I did not assert that primeval granite was derived from diorite. On page 9 we find : "It is probable that the primeval crustal magma was between syenite and diorite in composition, with about 60% of combined silica and without water." The effect of the absorption of water appears to have been to break up certain silicates, especially the ferro-magnesian, freeing silica and bases such as FeO. The former combined with water and, as silicic acid, leached from the magma those silicates most soluble in it, especially those containing potash, and such ore minerals that were present as it could dissolve under the conditions. Those practically insoluble in silicic acid remained behind in the basic portion of the magma ; examples of these are magnetite and chromite. The bulk of the sparingly soluble sulphides were also left behind. Water appears to divide a rock magma into an acid and a basic portion and the ultimate residue is practically non-siliceous ore. Crystallization differentiation and gravitative segregation are both equally incompetent to furnish the force necessary for the dissociation of silicates and the entire removal of silica from combination with bases. There must be some basic radicle present which has a greater affinity for silica than have the bases that are liberated. The only compound present capable of effecting the changes observed in nature I believe to be water, which, as hydroxyl, seems to have a strong affinity for silica.

It appears improbable that primeval magma could have contained free silica. Mr. Kendall asserts that the basic rocks do not contain free bases with which the free silica in granite could have combined originally. It is impossible for us to ascertain the quantity of free bases existing in basic rocks because the great bulk of them is not within our reach. The quantity of free silica in existence is certainly very large, but it makes a great show, for it is a leading component of the lighter rocks forming the greater part of the immediate surface layer of the earth. If Mr. Kendall realizes that the bases in calcium carbonate

and sodium chloride as well as magnetite, to mention only three substances common on the surface, were originally combined with silica, he will probably admit that the conclusion he has arrived at on this subject is not at all a safe one.

If the primeval crustal magma, as I believe, was an anhydrous silicate melt at its commencement it is practically certain that it contained no free silica. When water was absorbed the modification of the affinities of component radicles brought about by the presence of hydroxyl would lead to the formation of many new minerals whose existence was previously impossible, such as the micas. These were not confined to such as contained hydroxyl. It is doubtful if felspars, and particularly the the alkali felspars, could have come into existence in appreciable quantity in an anhydrous silicate melt.

The subject of magmatic differentiation is one on which there is much divergence of opinion, and concerning which it is easy to arrive at false conclusions. It is most regrettable that we have no geo-physical laboratory in Britain, for it is only by means of experiment that we are likely to ascertain the truth.

We now come to the definition of primary ores. While professing not to do so, Mr. Kendall uses the same criterion as I do, namely, genesis, in defining ores. All metals came up in solution in magmas in the first instance. They appear as ores only after magmatic segregation, and all must fall into one of two classes : (1) Those segregating as such within magmas, and (2) those expelled from magmas in solution and deposited usually in fissures either near the periphery or in overlying sedimentary rocks. Mr. Kendall says a primary ore is one " which has not been derived from any other ore." Since such ores must of necessity belong to one of the two classes mentioned above it follows that Mr. Kendall's definition and mine must have exactly the same meaning.

Mr. Kendall asserts that a pressure of 3,000 lb. per square in. would have prevented the expulsion of mother-liquor from the primeval crustal magma. Many granite batholiths demonstrably solidified under a depth of sediments which in hydraulic head only produced a pressure at the periphery much greater than 3,000 lb. per sq. in., yet we have evidence that such magmas gave off mother-liquor in every known case. The expansive force exerted by magmas on solidification is enormous.

Mr. Kendall doubts that magmatic liquids (1) removed the bulk of ore minerals from an acid magma, and (2) were the vehicle in which primary ores were transported to veins. Let us take the case of Cornwall, which is well known to most of us. How much tungsten, tin, or copper is found in components of the granite ? Practically none. Before consolidation of the granite these metals must have been disseminated in solution throughout the magma. It is not possible to explain their existence in the position in which we find them unless we admit that they were segregated by some means from the magma leaving barren granite, expelled in liquid form with silica, water, and other minor constituents in what we call mother-liquor, and that this, under favourable conditions yielded the ore minerals that we find in fissures both in the granite near its periphery and in overlying sediments.

The immediate cause of the development of ore minerals from magmatic liquids is not understood. I have not neglected the precipitating effect of substances in the walls of fissures as Mr. Kendall asserts. I refer to it in the last paragraph under " temperature of deposition " on page 19. Such cases as those cited by my critic are exceptional and no generalization can be based on them.

In Burma we have fissures filled with wolfram and quartz that have been reopened and the new space filled with chalcopyrite and quartz, reopened a second time and filled with pyrrhotite, blende, galena, stibnite, and quartz. This demonstrates clearly that the granitic magma gave off mother-liquor containing not only tungsten, but copper, zinc, lead, and antimony, and that in each case the ore minerals are accompanied by silica. I state this in order to demonstrate that the magma gives off in mother-liquor not only the high but the intermediate temperature ores by the same vent, and the latter in some cases at a later period than the former.

To the first paragraph on page 275 I cannot reply ; it is enigmatic.

In spite of Mr. Kendall having quoted the paragraph in which I define the scope of my paper, he insists on bombarding me with examples of ore deposits of types to which I made no reference. I purposely limited myself to ores occurring in veins

in order to present the problem of ore deposition in its simplest aspect.

Some of the types referred to by my critic, for example, that at Leadville, are probably not primary in the sense in which I use the term. Many galena and other sulphide ore deposits that I have seen I regard as not rigidly primary but secondary, due to replacement that acted in the same way as that by which chalcocite and galena were introduced into sedimentary rocks such as the "Red Beds" of the south-west United States, and Permian and Triassic beds elsewhere.

Concerning the origin of ores in veins in and near the periphery of batholiths, there can be little doubt, but the problem increases more and more in complexity as the deposits are farther removed from their source in igneous rocks. The genesis of ore deposits cannot be studied satisfactorily except by working up from the simplest, near igneous rock, to the more complex at greater and greater distances away. Many deposits usually regarded as primary may be really secondary, the result of metasomatic replacement by ore-bearing solutions produced by the dissolution of primary deposits by agents very different from those contained in magmatic liquids.

Though outside the range of my paper, I may remark, in connexion with some of the examples given by Mr. Kendall, that the present form of vein walls and the composition of vein matter, both as regards ore and gangue minerals, may be very different to-day from what they were when deposited. Many strata containing ores have undergone metamorphism, and it is quite evident that marked alteration, in form and composition of both walls and contents, may have resulted.

Manjak

The Editor:

Sir—In your issue of April last, in an article on the "Oil Resources of South America," by Mr. Henry B. Milner, the following statement occurs: "Glance Pitch, a variety of asphaltite, is a natural desiccated petroleum produce, which, when free from mineral matter, is known as 'manjak.'" I hardly think that the name manjak is of such wide application. It is not so used by Clifford Richardson in his treatises on the various hydrocarbons and allied substances, nor by Heinrich Ries, in his "Economic Geology." And is not found at all in the publications of United States Bureau, edited by the late G. H. Eldridge, their recognized authority on the hydrocarbon series.

As a matter of fact, the term manjak originated in the island of Barbados, and was never used outside that area until the neighbouring island of Trinidad struck a grade of glance pitch to which the Barbadian term was promptly applied, paying us the compliment of this sincerest flattery. The term is as distinctive of certain particular grades of glance pitch found only in Barbados, as is the term "Demerara crystals" of a particular class of sugar, and that notwithstanding the adoption of it by Trinidad, whose product does not enter into competition with that of Barbados. To the trade, the products are known as "manjak" and "Trinidad manjak."

Although manjak does claim to be of great purity (and in a report on it by the Mineralogical Bureau of Bohemia, it is stated of one of the grades that "it is surprising to find a bitumen of such purity in nature"), yet it does not claim to be "free from mineral matter." In fact, Mr. Milner seems to contradict himself when he applies the term to a product of South America, which he states "contains *only* 3% of mineral constituents."

BOOK REVIEWS

Oil Land Development and Valuation. By R. P. McLaughlin. Cloth, octavo, 200 pages, illustrated. Price 18s. net. New York and London: McGraw-Hill Book Company.

There are comparatively few phases of the mining industry calling for such specialized knowledge and technique as oil land development, and those who are unfamiliar with the vicissitudes of oil production can form but a small idea of the difficulties and responsibilities entailed in "running" a field successfully, the unenviable task of the average field manager. If things go wrong, as they may often do, there are two parties upon whom the blame may be conveniently fastened by inexorable directors, the geologist and the field manager; the former bears the initial brunt of adverse criticism if his

locations of well sites prove unprofitable; or if an unkind fate decrees the absence of oil at anticipated horizons; the latter, once some wells are brought in successfully, has to look to his laurels should drilling contractors give trouble, production slacken, or unaccountable failure overtake the operations of the company concerned. In either case the lot is not an easy one, and reputations are speedily made or broken as chance decides. The geologist, however, has an advantage, in that public opinion has of late been much enlightened by an extensive literature describing his work, which, intelligently perused, has brought home to the uninitiated some of the difficulties he has to face; the field manager and those who, with him, share the responsibility of development and production, have few volumes accurately descriptive of their work, and consequently less is known generally about such matters as well-drilling, water and gas troubles, cementing, casing, bailing, and shooting wells, output charts, production reports, and the like. The reason for this is not far to seek; competent field management is only won by long experience, and the nature of operations in different fields is often so variable that probably no single exposition by any one author would be adequate to all cases. Yet Mr. McLaughlin has undoubtedly given us a book which presents this aspect of the oil industry in a most concise and practical manner, and this volume cannot fail to be of the greatest use and enlightenment to all concerned with the development and successful administration of oil properties.

The author was formerly State oil and gas supervisor of California, and the foundations of this work are laid chiefly on experience gained in Californian fields; those who know anything about the technology of these oilfields know how diverse are the conditions of oil occurrence in that region, so that the author's contention that the principles involved in oil production there are applicable to all oilfields, though a somewhat sweeping statement, is one with which few will disagree.

The various phases of oil land development and valuation are grouped together under six main sections dealing successively with development programmes, drilling of wells, underground information derived from well-logs, oil production, repairing, deepening and abandoning wells, and values of oil properties. In all cases the principles involved are clearly discussed and some excellent diagrams appear in the text in illustration of the ideas involved. The ten sketches depicting flooding of oil wells by water, due to various causes, are especially good (Chapter II), and our only criticism in this connexion is that there might be more figures like them (publishing costs permitting!) explanatory of other possibilities of bad wells. The author has a good deal to say on sampling wells, that most important branch of drilling; he agrees with most observers in remarking that cable tools on the whole yield better samples than rotary, but he rightly draws attention to many difficulties in the way of procuring representative samples of strata, no matter what system is employed. In view of the increasing importance of microscopical investigations of the materials brought up, from both petrographical and palæontological standpoints in identification and correlation of horizons, it is to be hoped that manufacturers and others engaged in the production and manipulation of drilling plant will keep this in view, either perfecting existing sampling devices or so modifying the commonly used bailer for the collection of cleaner and less contaminated material than is customarily obtained thereby.

In the paragraphs on assembling of information, the construction and analysis of well records are discussed, and graphic well logs explained; an interesting feature is the use of "peg models," that is, models of wells of a given field made of wooden rods fixed into a firm base, the rods being coloured in sections representing thicknesses and differences of strata passed through; correlation of horizons from one well to another is effected by using fine string, and thus the structure of the field and the differentiation of producing horizons may be usefully portrayed. Such a model exists of the Coyote Hills Oilfield, California, and is here illustrated (p. 71).

The remainder of the volume calls for little remark, save that the final chapter on the value of oil land is somewhat brief in proportion to its importance; several references are given, however, to other and more detailed works published in America.

Of all the various works published hitherto on oil technology, there are just four of particular merit which we should like to see compulsorily laid on every petroleum company's board-room table; Mr. McLaughlin's volume is one of the "big four."

H. B. Milner.

Manganese. Pamphlet, 151 pages. Price 3s. 6d. net. London: The Imperial Mineral Resources Bureau.

This is a report, one of a series, dealing with the mineral industry of the British Empire and Foreign Countries, and published by the Imperial Mineral Resources Bureau.

While manganese minerals and alloys have been necessary in steel manufacture since the introduction of the Bessemer process, they became important factors to the Allies during the war period, by reason of the difficulty of obtaining supplies of the raw material, consequent on the activity of submarines, and also because no equally efficient deoxidizer of the steel bath was available.

Since 1913 much information has been published on the subject, particularly in the United States, and the monograph is a painstaking and complete compilation of this material with that previously published considered of sufficient interest to include in the publication.

The value, however, of a volume like the one under review is somewhat reduced by the fact that the information is not contemporaneous, and represents the viewpoint of many different observers. These disadvantages are evident when dealing with economic details, some of which, owing to being somewhat out of date or relating to the war period, have a reduced present or future value ; and also when discussing estimates of ore reserves.

The preface indicates that the volume will be published annually, and it is hoped that with the help of the Foreign Commissioners of the recently created Department of Overseas Trade, as well as of our Diplomatic and Consular representatives, it may be possible in future to publish reliable statistical and economic information shortly after the period to which it refers, in addition to that of a more general character which appears from time to time in the proceedings of scientific institutions and in the technical press.

Under the heading " General," interesting particulars are given regarding the principal minerals, their uses and value for different purposes. The statement on page 7, regarding the mineral utilized in the manufacture of iron and steel is hardly correct, for a large percentage of 50% manganese ore is smelted in the blast-furnaces, as indicated on page 27, for the production of a pig iron containing 1 to 2% of manganese, which enables the basic process to be more easily worked.

It is noteworthy that the present prices of manganese ore and alloys are within reasonable distance of those of the pre-war period, this being due to the trade depression, and the great reduction in the cost of ocean transport. Further reduction in costs will, no doubt, be obtained as a result of lower railway rates, and the more general application of mechanical plant to the getting of the mineral, particularly in India.

During the war ferro-manganese was made in many countries not hitherto producers, and on a larger scale than heretofore in the United States, so it is probable that this will influence prejudicially the British production of ferro alloys by the imposition of protective duties.

No mention is made of the use of manganese ore for the production of carbon-free metallic manganese, made by the thermit process, which is becoming of increasing importance for nickel, copper, and silver alloys.

Under the title " World's Production," some interesting information is given, but the estimates regarding costs of production of Indian, Brazilian, and Caucasian ores, taken from Dr. Fermor's book published in 1909, have now only historical value. The three Indian deposits, of which estimated reserves are given, did not contribute appreciably in recent years to the output, and other properties of much greater importance exist in the Central Provinces of that country. So little development work has, however, been carried out on any of them that any estimates must be only approximations, although those who have seen the ore-bodies are convinced that the potential reserves are very large.

With regard to the Brazilian deposits, the principal one, Morro da Mina, has been recently acquired by the United States Steel Corporation, and as that concern requires in periods of industrial activity upwards of 500,000 tons per annum of manganese ore for its own consumption, it is probable that amount will be obtained from the deposit in the future.

The present capacity of the world's steel-works is about 100 million tons per annum, which, together with other demands for manganese, will require in times of good trade nearly 3 million tons of ore. This can easily be supplied by known deposits, if transport arrangements are available. At present steel is only being produced at the rate of about 35 million tons per annum, so

that the absence from the market of Caucasian ore is not seriously felt. With the return, however, of favourable trade, there may be a scarcity of rail and ocean transport for Indian and Brazilian manganese ore, unless political conditions in the Caucasus become more settled.

The details regarding the Sinai deposits indicate that although occurring at the base of the Carboniferous Limestone series the mineral may be classed as a manganiferous iron ore containing about 40% manganese and 15% iron, similar to that of the lateritoid deposits of India, Brazil, and elsewhere. The West African deposits at present known are important, and it is probable that others will be discovered in the district as the forest coast belt is cleared. The South African and Canadian deposits are unlikely to provide mineral for export, but are probably of sufficient importance for local requirements; while the Australian deposits appear to be more extensive, although in many cases of the lateritoid type, and their distance from the coast and Europe precludes export, unless rail and ocean transport can be obtained at low rates. Dr. Fermor's classic work has been drawn upon for particulars of the Indian deposits and analyses of the ores.

Of the foreign sources of manganese ore, Georgia, South Russia, and Brazil are the most important. The Russian deposits are especially valuable by reason of their comparative proximity to steel producing countries and low percentage of iron contents which neutralizes the disadvantages of its finely divided condition consequent on its pisolitic and earthy character which is undesirable for the blast-furnace. Owing to the chaotic political position in Georgia it is doubtful when the mines of Tchiatouri will be in regular operation again, although cargoes from stock have reached Western Europe from the South Russian and Caucasian deposits. The deposits of high-grade ore of the Central American republics, Cuba, and United States, do not appear to be very extensive, as no great development of them took place during the war period when the incentive of high prices and national stress should have enabled this to be done. Of the Brazilian deposits in Minas Geraes only that of Morro da Mina has extensive reserves, and is capable of a large output, although several other properties can produce when prices are satisfactory.

H. K. SCOTT.

NEWS LETTERS

MELBOURNE

June 30.

GOLD STEALING IN WEST AUSTRALIA.—A deputation, which included representatives from the Primary Producers' Association, the Chamber of Mines, and the Mining Association, waited on the West Australian Minister for Mines, Mr. Scaddan, early in June for the purpose of urging the necessity of steps being taken to cope with the illicit traffic in gold. The deputation was introduced by Mr. T. H. Harrison, M.L.A., and the principal speaker was Mr. Richard Hamilton, president of the Kalgoorlie Chamber of Mines, who presented a Bill which had been drafted, not with a wish to usurp the functions of the Minister's department, but to save the Minister a lot of time and trouble. He thought the public, and perhaps Parliament, did not appreciate the extent of the evil of gold stealing. If as much value had been stolen in wheat, steps would have been taken to stop the practice. The price of six bags of wheat could be stowed away in a man's mouth in the form of gold without any inconvenience to the man; hence the difficulty of detecting the thefts; for years and years the value of 100,000 bags of wheat had been stolen from mining companies, and they had tried in vain to get prohibitive legislation passed. The Minister, in reply, concurred as to the neglect of successive Cabinets to deal with the matter. The matter was not new, either to him or to his department. He did not know how far the deputation's draft Bill would meet the case, but he would have a Bill embodying the idea prepared, and would consult the Chamber of Mines respecting it. He could not promise that it would be put before Parliament this session, but it would be submitted to the Cabinet, and it would have a good chance of being dealt with this session.

QUEENSLAND GOLD MINING.—The official figures for the month of May, 1921, indicate that the production of gold in Queensland is at a very low ebb, probably the lowest since gold mining has been a recognized industry in Queensland. The chief cause of the falling off was the closing down of Mount Morgan, no gold being won there for the month, as against 6,346 oz. for May in the previous year. Industrial troubles among the workers account in a fair measure for the lessening of the yield,

and scratchers and fossickers are not so numerous as in the years gone by, when they were lured to fields of possible fortune. Last month's output was 2,077 oz., against 8,432 oz. for May, 1920. Charters Towers dropped by 299 oz. to 776 oz.; Gympie increased from 237 to 722 oz.; Chillagoe from 173 oz. to 267 oz.; Etheridge and Oaks fell from 175 oz. to 147 oz.; Croydon, 166 oz. to 74 oz.; Ravenswood produced 72 oz. in both periods. The total yield for the five months to May 31, 1921, was 24,986 oz., being a decrease of 11,701 oz. against the five months of the same period in 1920. The dividends for the five months this year amounted to £4,500, against £49,663 for the same period last year.

MOUNT CUTHBERT COPPER.—During the half year ended February 28 only 63 days' actual work was done at these mines north of Cloncurry, distributed over October, November, and December, and on December 18 the mines and smelter were closed down. As costs and the price of copper have not since adjusted themselves to give a working profit, the mines and smelter remain closed. The amount of blister copper produced during the half-year was just over 693 tons. Of 12,468 tons of ore smelted about half (6,285) came from the Kalkadoon mine, the Mount Cuthbert mine furnishing 3,166 tons, the Orphan 2,415 tons, the Mighty Atom 510 tons, the Surprise 79 tons, and the Little Wonder 13 tons. Since smelting was commenced the total of ore treated has been 123,093 tons, from which 6,768 tons of blister copper was produced. Before the company's own smelter was put up 13,099 tons was smelted at Mount Elliott, which yielded 1,110 tons of blister, making the total tonnage smelted 136,192, for a production of 7,878 tons of blister copper. No fresh estimate has been made of the ore reserves, owing to the limited amount of extraction, and these still stand at 193,500 tons containing 13,245 tons of copper. These figures include 80,000 tons in the Kalkadoon mine, averaging 5% of copper, and there is, in addition, 35,000 tons of limestone flux in the Kalkadoon east lode, averaging 2% of copper. Only 509 ft. of actual development work was done during the half year, but the results are regarded as satisfactory. Chief interest lies in the developments at the Orphan mine, where, at the 100 ft. level, the new ore-body was proved for a length of 231 ft., while the south end was still undeveloped, and the average width was about 20 ft. On the west lode the length of the ore exposed was 255 ft., and the lode was still strong in the north end. The ore in the north drive is regarded as payable. At a depth of 175 ft. the south level was 325 ft. in fair ore, and the face was in ore of high grade.

PERTH, W.A.

August 1.

SUGGESTIONS FOR REFORM.—"The early history of California, New Zealand, Victoria, and West Australia itself have strikingly illustrated the potency of discoveries of gold in stimulating the flow of population and capital into a country. The gold-mining industry has been the main factor in the progress of this State, and the Government should be urged to take immediate steps in the direction of bringing about a revival of that industry." This is the preamble of a notice asking mining men in West Australia to meet and formulate a series of recommendations to the Primary Producers' Association. For some years representatives of goldfields constituencies have devoted their energies to securing benefits for the workers, without giving any consideration to the rights of the owners. However, the general depression in mining has wakened up the primary producers to the fact that something must be done, if the mining industry is to survive. The Chamber of Mines in Kalgoorlie and the Mining Association in Perth have been co-operating in this, and already several suggestions have been made which it is hoped will be introduced to Parliament in the Session just opened. I have in a previous letter dealt with the evidence given by various mining men before the Federal Royal Commission on Taxation. It is expected that an amelioration of some of the anomalies will be secured, such as the taxing of prospectors when they make a find and on the taxation on the transfer of gold-mining leases, both of which are grossly inequitable.

GOLD STEALING.—A gold buyers' bill has been prepared, which will make it very difficult for the receiver of stolen gold to dispose of it. At the present time if a man has a mine, in which rich patches of ore occur, he can augment these by adding stolen gold, without much fear of detection. Under the new bill, if such a mine were suspect, the Warden could order it to be sampled and secure evidence which would enable the police to put the onus of proof

of production on the owner. Recently one such man was caught bringing to the mine 1,000 oz. of amalgam, after midnight. He was arrested, convicted, and sent to gaol for eight months and the gold forfeited. The new bill, it is considered, will go a long way to stopping the gold-stealing evil, in that it will make the receiver's risks too hazardous to be worth taking.

LABOUR QUESTIONS.—The Arbitration Court, which was heralded as the panacea for all troubles by the workers, has resulted in a professional class of advocates whose aim seems to be to keep employer and employee apart. It is now suggested by the committee who waited on the Premier yesterday that as soon as any industrial trouble arises a conference of owners and workers shall be held, under a chairman to be chosen. Each side can state its case, and in this round-table conference it is felt that a better understanding will be come to, than if the case were to be fought on the present lines. It is only the questions which cannot be mutually settled that will be heard by a Supreme Court judge. It is suggested that he be appointed for life, and thus ensure continuity in arbitration work.

The writer has during the past five years been in a position to compare the effects of class warfare on the one hand and co operative working on the other. In the first the costs are high, and neither the employer nor employee is satisfied. In the latter, where everyone works together to make a success of the scheme, it is progressive and financially sound. The latter are men who learnt the value of team work in Gallipoli, Egypt, France, and Belgium, and although some of these men are crippled they are succeeding where other industries are being damaged through want of understanding between the owner and worker. Col. Blackett, at the annual dinner of the Institution, sounded a note that will echo in the hearts of mining engineers the world over, when he spoke of his love for the Durham coal miner. The miner individually, whether he be a coal miner or a gold miner, is a most lovable man ; one has only to see the response to an appeal for help, either in money or in service, when his purse and his life, if necessary, are willingly proffered. It is the professional agitator who is too lazy to work that causes all the trouble, because his living depends upon keeping the owners and workers apart. There are signs that the latter are beginning to realize that they are being led to destruction by the Bolshevistic element which secured control of the trades unions while the loyalist workers went to the war. The soldiers, when they returned, wanted peace, but find they must now fight the enemies in their midst (who stayed at home), if the industries of our fair land are to be saved.

SECURITY OF TENURE.—The subject of security of tenure of mining leases has also been given attention. It is suggested that the expenditure on development work on a lease shall be cumulative in the matter of exemption. That is, assuming £4,000 spent entitles a leaseholder to one year exemption, £20,000 should entitle him to five years, and mines on which a considerable amount of money has been spent may not be payable under existing conditions ; but with the exception of one year exemption, even although £100,000 may have been spent, without any reward, the owner is at the mercy of the Warden. If he fails to protect his lease for one day it may be jumped by any man of straw who comes along. Whereas, if the owner who has spent his thousands on the lease knew that he would be sure of being protected, he would be much more likely to find more money on the lease if conditions improved than the jumper would. There is no equity at all for the leaseholder under the present Act ; and although Ministers have hitherto been unable to see it in this light, perhaps some future Minister may be convinced by the pressing argument of loss of capital to the State which is manifest. A number of suggestions have been made, whereby the leaseholder would have rights more in accord with those granted to holders of other property.

TRIBUTING.—The result of the hasty legislation introduced last year by the Minister of Mines rather appropriately referred to by one manager as the " Tributers Extinction Bill," has been that the companies will not renew existing tributes nor grant new ones. A Royal Commission, with the Warden of Kalgoorlie as chairman, a member of the Chamber of Mines, and one from the Miners' Union, has been appointed to inquire into this question, and is now taking evidence. It is hoped that some workable agreement can be come to, whereby instead of a term of three years, which can now be demanded as the length of the tribute, irrespective of how impossible it may be for the owner, it is proposed that the

tribute agreement shall be subject to six months' notice of termination, which is much fairer. The terms will no doubt be made more equitable so that after the tributer has made wages the owner shall receive a fair share as royalty.

HAMPTON PLAINS.—Ives Reward, which is situated on the south side of Lake Lefroy, on the continuation of the line extending from Boulder through Celebration and White Hope, is being reported on by the manager of the last-named company. It is a big lode, on which glowing reports have been made by the prospector and manager. The report by this well-known mining engineer, N. E. Giblin, will therefore be looked for with keen interest, as it may mean another big mine. If so it would be an incentive to genuine work on a field which was born in a boom, and its development frustrated by companies with big share capitalization, but little working capital.

The prospector of the new Monger field, McCahon, who has done some good work on his lease, has cut the Monger Proprietary lode at a depth of 160 ft., and it is said to carry high values. A battery has been erected on the field, and no doubt a number of rich crushings will be secured from pipes of ore, but the mines are not suitable for companies, being more suitable to parties of working miners.

The reports from the Celebration recently have been anything but reassuring. The lode in the 300 ft. level, occurring as it does in contact with the jasper and porphyry, is patchy, and dispels any doubt as to its similarity in origin to the lodes at Boulder. It was questionable when this lode was found whether it was derived from the quartz-dolerite on the one wall or the porphyry on the other. Owing to the oxidation and alteration of the lode material it was impossible at the 100 ft. level to say from which of these wall-rocks the gold came. The majority of mining engineers and geologists who inspected the mine and the field were of opinion that the lode was identical with those on the Golden Mile. That opinion has proved to be wrong. At the same time there is no reason for the statements issued in a recent editorial in the *Times* that the reports were made by "two a penny mining men." It was the very fact that several leading mining engineers in West Australia were the vendors of the Celebration when it averaged 50s. over 20 ft. in width that caused the boom. It was the hundreds of companies that were floated on the strength of this property, on leases without any apparent ore-bodies, and not accompanied by a report by an accredited mining engineer, that was the greatest mistake. This applies also to the mines on the Mount Monger field, which was condemned by the writer in these columns right from the start.

FLOTATION AND REPORTS.—During the war companies could not be floated without the sanction of the Federal Minister dealing with this, and he insisted on a report being made by some reliable man as to the justification of that company and its prospects. Had this wise war-time measure been retained, only those leases on which a lode carrying reasonable prospects of gold would have been allowed to be floated, and the numerous wild-cat companies would never have come into existence. Whether the State Government will take this lesson remains to be seen; probably they will, as in the past, say it is not their business, but this it surely is if they wish West Australian mining to regain the confidence of the investing public.

OIL.—There was some wild excitement in Perth recently when a local paper published news that an oil flow had been struck at Bremer Bay, near Ravensthorp, and that the owners were claiming the reward of £5,000 offered by the Government for the discovery of a payable oilfield. Inquiries elicited the fact that the rumour arose because a boring plant had arrived to test several points where good surface indications were found. Considerable Tertiary and Post-Tertiary beds exist at the back of Bremer Bay, and it is here that the prospecting work is being carried on.

The Assistant State Mining Engineer (Mr. Torrington Blatchford) is still in the Kimberley district investigating certain oil indications there, which had been reported to the Mines Department. He has sent down several samples for preliminary examination, as a guide to his Geological Survey.

NORTHERN WEST AUSTRALIA. — The Government realizes the possibility of the great Nor' West of this State, and have appointed Major Drake-Brockman, an engineer, as a First Commissioner to reside there and collect information, with Mr. Blatchford as his mining adviser. Those men who have lived in that tropical portion of West Australia are all enthusiastic as to its mineral possibilities.

TORONTO

August 10.

Porcupine.—The gold-mining industry has entered upon a period of prosperity and expansion. Labour is plentiful and efficient, and operating costs are being steadily reduced by the adoption of modern methods and devices. The gold production of Ontario during the present year to date is estimated at about $7,600,000, of which approximately $6,700,000 was the output of the Porcupine camp. The Dome Mines during the three months ended June 30 realized net profits of $235,697, being at the rate of 20% on the issued capital. The grade of ore taken from the lower levels is much higher than that formerly treated, rendering possible larger returns to the shareholders. It is officially stated that the present dividend rate of 10% per year will be continued, and that any further distribution of profits will be in the form of a return of capital. The McIntyre has cut a vein 30 ft. wide stated to carry $20 to the ton on the 1,375 ft. level, which is being opened up. A station has been cut on the 1,625 ft. level, and the sinking of the shaft to a depth of 2,000 ft. is being continued. The management has decided to proceed at once with the construction of an addition to the mill, increasing its capacity from 500 tons per day to 1,000 tons. The production of the Hollinger Consolidated is about $800,000 per month, and dividends of 1% every four weeks continue regularly, the aggregate disbursements for the year amounting so far to $1,968,000. At the Porcupine Paymaster, situated about 2 miles south-west of the Dome, development is meeting with satisfactory results. The vein is 20 ft. wide in places and is paralleled by other good veins. The shaft will be put down to the 400 ft. level. Lateral work is under way at the 300 ft. level of the Beaumont, formerly the North Davidson, to cross-cut promising veins indicated by diamond-drilling. Development is being undertaken on the Gold Island property on Night Hawk Lake with A. R. Globe, formerly assistant manager of the Hollinger, as manager. The Allied Porcupine Mines has unwatered the Three Nations mine, which it recently took over, and will resume underground work. The March Gold is arranging to instal a mining plant, surface work having been attended with encouraging results.

Kirkland Lake.—The Lake Shore during June established a new high record, with a production of $52,539 from the treatment of 1,656 tons of ore, being an average recovery of $31·73 per ton. Present development work is being carried on at the 400 ft. and 600 ft. levels with excellent results. Dividends of 2% have been declared payable August 10 and November 10. The Ontario Kirkland is making good progress with the construction of its mill, which it is hoped will be ready for operation this fall. A new shaft is being made near the mill site by rising from the 300 ft. level to connect with a shaft started from the surface. The grade of ore latterly taken out by the Teck-Hughes is running high. A new grinding and classifying unit is to be added to the mill, which will increase its capacity from 100 to 160 tons daily. The Sylvanite mine is being taken over by the Kirkland Lake Proprietary (1919) conjointly with a group of American financiers. The unissued 80,000 shares of the present Canadian Sylvanite Co. will be purchased for $400,000, and the company reorganized with a total capital of $3,000,000 in shares of $1 each. Existing shareholders will receive $2,000,000 in the ratio of five shares for one, and the remaining 1,000,000 shares will be held in reserve, the Kirkland Lake Proprietary and the American group to have the option for two years of acquiring 500,000 shares each. The Wright-Hargreaves during June produced over $51,000, though the mill lost 25% of possible running time owing to power difficulties. The mill is now handling 150 tons of ore per day, mainly development ore. Stopes have been opened up in several parts of the mine. At the King Kirkland a new vein 7 to 10 ft. wide and heavily mineralized has been discovered by surface trenching. The drift at the 300 ft. level of the Bidgood has been in ore for upwards of 100 ft. Surface work at the Wood-Kirkland has uncovered several veins, one of which especially appears of considerable importance. Lateral work will be undertaken to cut these veins at the 100 ft. level. The Queen Lebel, a new company, capitalized at $2,000,000, has been formed to operate a group of claims on the south-east side of Gull Lake. An 8 ft. vein has been opened up at the surface.

Cobalt.—The silver-mining industry, though still depressed, is showing more activity, and the outlook is improving, owing to the strengthening in the price of silver, and more favourable economic conditions. It is still handicapped, however, by high freight rates, and a wage rate, which, notwithstanding the recent reduction, is

higher than many of the mines can pay with a margin of profit. The Nipissing during June mined ore of an estimated net value of $162,824, and shipped bullion from Nipissing and custom ores of an estimated net value of $208,526. The production of cobalt has become an increasing factor, the output of this metal in June (included in the above) being $25,560. The mill of the Mining Corporation of Canada is treating about 300 tons of ore daily, containing an average of approximately 20 oz. of silver per ton, indicating an output of about 2,190,000 oz. annually. The La Rose Consolidated is extending its operations, and has unwatered and resumed the development of the Violet property, adjacent to the O'Brien. The Hudson Bay is preparing to resume milling operations for the treatment of broken ore to the amount of 6,000 tons. When this is done the directors will decide whether to undertake further development or close down the mine. The Bailey custom mill during July operated at capacity, treating 4,043 tons of ore and realizing gross earnings of $12,129. The shaft on the Waldman property of the Oxford Cobalt is down 50 ft., placing some high-grade and a substantial quantity of milling ore in sight.

LIGHTNING RIVER.—A rich find of gold has been made on the claims of the Lightning River Gold Mines, Ltd., in Harker Township, 8 miles south of Lake Abitibi. The vein is 54 in. wide, with free gold across the whole width. The richness of the ore has caused much excitement, and a rush of prospectors to the district has commenced.

LARDER LAKE.—The large three-compartment shaft of the Canadian Associated Goldfields has been put down to the 350 ft. level, and cross-cutting towards large ore-bodies indicated by drilling has begun on the 175 ft. and 320 ft. levels. The company has been able to effect great economies in transport by the use of a caterpillar tractor, capable of carrying a load of 11 tons. The Crown Reserve of Cobalt is exploring its Larder Lake claims, and has uncovered an important vein system.

VANCOUVER, B.C.

August 20.

SILVER-LEAD.—With the exception of the activities of the two big smelting companies, both of which are being operated at close to capacity, mining in the Province remains quiet, although there has been considerable improvement during the past month. The Granby Consolidated Mining Smelting & Power Company is turning out about two and a half million pounds of copper monthly, and, judging from the fact that the company's engineers have examined several silver-lead properties recently, it would appear that the management is contemplating the addition of a lead smelting and refining department to its plant. In fact, there would seem to be an opening for such a plant on the northern coast of British Columbia. Great activity is being exhibited this summer at the Mayo camp in Yukon, and at the present time ores from there are being shipped to the Selby smelter, on San Francisco bay, a very expensive haul that is made possible only by the high-grade nature of the ore. More than two thousand claims have been staked in the Keno Hill district, near Mayo, and among the parties that are developing ground there are the Yukon Gold Company, and F. W. Bradley, of the Bunker Hill and Sullivan. The ore that has been shipped is a high-grade silver-lead ore, running about 200 oz. in silver and 60 to 70% of lead. Of course, there is a quantity of ore of a much lower grade, and the Yukon Gold Company is contemplating the erection of a concentrating plant next year. This camp, together with the Salmon River and Alice Arms camps and the recent discovery of silver-lead ore in the Atlin mining division, would seem to warrant the erection of a lead smelter on the coast in the northern part of the Province, and no one is better fitted to undertake the enterprise than the Granby company, which already has an excellent staff of trained metallurgists at Anyox.

PREMIER GOLD.—The Premier Gold Mining Company has put the first 100 ton unit of its combined concentrating and cyanide plant into operation, and it is said to be giving complete satisfaction. A quantity of concentrate has been sacked, ready for shipment, but at the present time the condition of the road between the mine and tide-water prevents it being moved. The construction of the aerial tramway, which will be $11\frac{1}{2}$ miles long, is being pushed, and ore-bunkers are being built at Stewart, the shipping point. A rather wet summer, and consequent soft condition of the roads, has delayed the work appreciably. The Fish Creek Mining Co., which is operating a mine on the Alaskan side of the international boundary, has sent a trial shipment to the

Selby smelter, and has some 20 tons of ore sacked ready for shipment over the winter snows. The ore from this mine is said to be similar to the Premier ore, containing gold and silver, and having an assay-value of between $500 and $600. Like the Premier, too, the property is rather inaccessible, high up on a mountain, and for the present will have to depend on winter snow for the transport of its ore. The Alaskan Government, however, has made arrangements for the building of a waggon-road to the mine. Probably more than 100 tons of ore will be taken from the property during the coming winter.

Dolly Varden.—The Dolly Varden mine, which produced some 850,000 oz. of silver last year, is in litigation once again. It will be remembered that, in the closing hours of the 1920 session of the Provincial Legislature, an Act was passed taking the mine out of courts and vesting its ownership in the Taylor Mining Company. Among the liabilities that the Taylor company had to assume was a mortgage on the property for $150,000, given by the previous owners, the Dolly Varden Mines, Ltd., to George Wingfield, of Reno, Nevada, who was president of the company. This mortgage fell due on July 31, and Mr. Wingfield is suing the Taylor Mining Co., the Taylor Engineering Co., and Charles M. Rolston, of Vancouver, for the amount together with accrued interest, which brings it up to $182,322. The plaintiff asks for an accounting, for foreclosure, for possession, and for the appointment of a receiver. The president of the Taylor Mining Co. paid a visit to England last winter, it is stated for the purpose of raising funds for the erection of a concentrating and cyanide plant to obtain more economical production. No announcement was made on his return, so, presumably, his mission, if such it was, failed. Neither the railway nor the mine was opened this spring, but a few weeks ago the railway was put into operation for the purpose of shipping some 3,000 tons of ore that was mined, but not shipped, last year. A little development work was started, and this has resulted in the discovery of another ore-body, some 20 ft. above the old workings. The extent of the new discovery has not yet been determined, as it is covered by a rock slide, and a considerable amount of work will be necessary to discover its extent. A sampling across 4 ft., however, gave an assay of 57 oz. of silver per ton, while picked samples ran up to 267 oz.

The Consolidated Mining & Smelting Company is maintaining the production of lead and zinc from its Sullivan mine, at Kimberley, and considerably increasing the production from its Rossland mines, which contain essentially gold ores, with just about sufficient copper for the collection of the precious metals. The copper output from the smelter will be small, probably less than four million pounds, but the gold, silver, lead, and zinc outputs should be considerably in excess of last year, as the total tonnage treated at the smelter up to the middle of August was 260,924 tons, compared with 383,112 tons for the whole of last year. With the exception of about 5,000 tons, all the ore has come from the company's own mines. The Consolidated company has two surveying parties exploring what is known as the Esquimalt & Nanaimo land grant, on Vancouver Island. This belt of land was granted to the Canadian Pacific Railway by the Dominion Government in consideration for the construction of the railway, the Consolidated being to all intents and purposes a subsidiary of the C.P.R. The monopoly of this belt of land has deterred prospecting on the Island, and last year the Provincial Minister of Mines took the matter up with the C.P.R., with the result of the present survey, which will determine exactly what ground the company desires to retain. The remainder will be turned over to the Provincial Government, and will be opened for location.

Other Mines.—The new concentrating plants at the Le Roi No. 2 at Rossland, and the Ottawa mine, at Slocan, have been put into operation, and are said to be working satisfactorily. Several properties in the Slocan have either changed hands or been leased or optioned, and a good deal of development and explorative work is being done, but little actual production.

Limonite. — Part A of the Summary Report of the Canadian Geological Survey, which has been issued recently, is of particular interest to British Columbians, in that it contains a report of the limonite deposits in the Taseko valley, in the Lillooet division. Considerable excitement was caused in 1919 by the announcement of the discovery of an immense deposit of limonite. W. M. Brewer, one of the district engineers connected with the Provincial Department of Mines, was sent to make a reconnaissance of the deposit. From such a reconnaissance he was rash enough to make an estimate that

the deposit contained upwards of seven million tons of actual ore and fifty million tons of possible ore. To confirm this the Provincial Department of Mines sent F. J. Crossland, an independent mining engineer, to make a thorough examination, while the Geological Survey sent J. D. MacKenzie for the same purpose. Both engineers spent the greater part of last summer in the field, and their estimates, which agree closely, place the actual ore at little more than 650,000 tons. This ore is distributed in isolated patches over an area of some 50 square miles, and, owing to the inaccessibility of the situation, is of no commercial value.

PERSONAL

W. H. GOODCHILD has left for Kirkland Lake, Ontario.

B. B. GOTTSBERGER has been elected secretary of the Mining and Metallurgical Society of America. He is a Columbia man, and one of his first appointments was on the staff of the El Oro company. In 1900 he became assistant to J. Parke Channing at the Tennessee Copper Co's. properties, and became manager in 1906. In 1909 he was transferred by the same interests to the Miami, where he was manager for ten years.

A. J. HALE has been appointed professor of applied chemistry in the Finsbury Technical College.

DR. ARTHUR HOLMES has been on a brief visit to London, and has returned to Burma, where he will take up the duties of manager of the Yomah Oil Co. (1920), Ltd.

C. C. LEACH has been elected president of the North of England Institute of Mining and Mechanical Engineers for the coming year.

OWEN LETCHER, editor of the *South African Mining and Engineering Journal*, has gone to India on a three months' visit.

P. B. McDONALD, of New York, has been touring Germany and France.

W. H. MARDALL is resigning the position of secretary to the Johannesburg Consolidated Investment Co., Ltd.

LAURENCE PITBLADO has left for Chile.

RICHARD QUANCE has left for West Africa.

C. A. RICHARDSON is here from Cobalt.

A. T. SNELLING has gone to Mongu, Nigeria.

G. GORDON THOMAS is expected next month from Nigeria.

F. H. TONKING has gone to West Africa.

DAVID WILKINSON is here from Johannesburg.

A. STANLEY WILLIAMS has left for Nigeria.

J. NORMAN WYNNE has left for the Pahang Consolidated Company's mines in the Federated Malay States.

H. H. YUILL, of Bainbridge, Seymour & Co., Ltd., is visiting the Shetland Isles.

HERMANN LANDAU, a stockbroker well known in former years in connexion with West Australian mining, died on August 23.

SIR SAMUEL C. DAVIDSON, head of the Sirocco Engineering Works, Belfast, died on August 18. He started life as a tea planter in northern India, and while engaged in that industry came to the conclusion that mechanical methods should be introduced. His most important invention was the Sirocco fan, designed for the purpose of drying the tea leaf. In 1881 he started the manufacture of this fan and other specialties at Belfast. As is well known, the Sirocco fan has nowadays many other applications than tea drying, and it is as widely used for mine ventilation as for the purpose for which it was originally designed.

THE LATE WILLIAM CROSLEY. As briefly announced last month, William Crosley died at the end of July. He had returned only recently from Nigeria, and was completing his arrangements to go out to the Gold Coast when an attack of heart failure carried him off suddenly in London. He came of a family of civil engineers, his father having been associated with the construction of some of the earliest railways in England. For the greater part of his career he was engaged in gold mining, but in his earlier years he gained a practical knowledge of engineering in colliery work, his first responsible post being as chief surveyor to the Pemberton Collieries, near Wigan. In 1887 he transferred his activities to gold mining, going out to take charge of the Sucré gold mines in Colombia, South America, which post he held for ten years. He then went to Rhodesia as manager for the Rhodesian Gold Trust, afterwards acting as consulting engineer to the Charterland Gold Fields and the Mashonaland Agency. From 1904 to 1909 he was on the Gold Coast in charge of the Prestea Block A. For the following three years he was engaged in exploration work in Mexico, travelling over many parts of the country to report on mines and properties. Circumstances then recalled him to Prestea, where he spent three strenuous years developing and reorganizing the mine and the native village. During the war he was engaged in Burma developing wolfram mines. The last year of his life he was in charge of a group of tin mines in Nigeria for Tarbutt & Janson, from which post, as above stated, he had only recently returned at the time of his death. In the intervals between these long engagements he reported on various mines in the South of France, North of Spain, and Portugal. Besides being a mining engineer of high repute, it is interesting to record that Mr. Crosley was an artist of considerable ability. His sketch-book was invariably packed with his luggage, and he contributed several articles and reports for scientific and official purposes, illustrated with beautifully executed sketches. He was a member of the Pastel Society, and his work has been exhibited at their shows in London for several years past. He had completed a handbook on surveying for the use of settlers only on the evening previous to his decease.

TRADE PARAGRAPHS

F. A. WILKINSON & PARTNERS, LTD., of Hatfield, are making small wind-power electric generating plant.

T. L. REED COOPER, of 11, Tothill Street, Westminster, has issued a new catalogue of his immersible electric pumps.

EDGAR ALLEN & CO.'s works at Sheffield are described and illustrated in *Engineering* for August 19 and 26 and September 2.

The HARDINGE COMPANY, of New York (London office, 11-13, Southampton Row), have issued No. 6 pamphlet on Grinding Data, dealing with eight-foot ball-mills.

The METROPOLITAN-VICKERS ELECTRICAL CO., LTD., of Manchester, and 4, Central Buildings, Westminster, send us Circular 1790/1, dealing with motor equipments for main rolling-mill drives.

F. W. BRACKETT & CO., LTD., of Colchester, have issued a bulky catalogue dealing with air-compressors, dry vacuum pumps, wet vacuum pumps, plunger pumps, centrifugal pumps, and steam engines.

The INGERSOLL-RAND CO., LTD., has been registered at Somerset House as a private limited company to carry on the English business of this well-known American corporation. W. M. Treglown is chairman, and D. M. Armstead is manging director.

HENRY BATH & SON, LTD., metal and mineral brokers, of London, Liverpool, and Swansea, send us a copy of conversion tables containing factors for converting cents per pound into pounds per ton, according to the variations in the dollar exchange.

NOBEL INDUSTRIES, LTD., of Nobel House, Buckingham Gate, London, S.W. 1, send us three new pamphlets: Blasting in Collieries and Hints on Electric Shot-Firing; Blasting Explosives and Accessories; and Ground-Clearing with the aid of Explosives.

The BUCYRUS COMPANY, whose headquarters are at Wisconsin, U.S.A., and who have hitherto been represented on this side by Messrs. G. F. West & Co., announce that they have now opened their own London office at 19, Iddesleigh House, Caxton Street, Westminster, S.W. 1, to which address all communications should in future be forwarded.

The METROPOLITAN-VICKERS ELECTRICAL CO., LTD., of Manchester, and 4, Central Buildings, Westminster, send us their circulars 1,266/1, 1,266/2, and 1,254/1, dealing respectively with oil circuit breakers type G2, oil circuit breakers type G11, and the breaking capacity of switches and circuit breakers.

HEAD, WRIGHTSON & CO., LTD., of Stockton-on-Tees, and 5, Victoria Street, Westminster, are re-issuing their catalogue of mining machinery in sectionalized form. The sections already received deal respectively with jaw-crushers, crushing rolls, grinding pans, Nissen stamps, the Colorado impact screen, the Notanos tube-mill, the Colorado rod-mill, the Colorado convertible-discharge ball-mill, the Akins classifier, the Lowden patent dryer, the Notanos patent rotary dryer, and the Skinner patent roasting furnace.

G. A. HARVEY & CO. (LONDON), LTD., of Woolwich Road, and Suffolk House, Laurence Pountney Hill, London, are exhibiting their specialties at the International Shipping, Engineering, and Machinery Exhibition at Olympia: Perforated metals for all industries, with over 3,000 designs; colliery and quarry screens; perforated conical slotted copper for sugar centrifugals; perforated brass radiator and pipe guards; ventilating panels and piping; storage tanks; steel lockers and cupboards; steel storage bins; heavy mild steel hoppers and cyclones; transformer tanks; sheet steel and plate work of all descriptions.

JOHN & EDWIN WRIGHT, LTD., of the Universe Rope Works, Birmingham (London office, Salisbury House, E.C. 2), have a representative show at the International Shipping, Engineering, and Machinery Exhibition, Olympia. The exhibit includes highest quality steel-wire ropes, for the engineering, marine, mining, oil well, and logging industries, including locked coil, flattened strand, non-rotating, and other special constructions of wire ropes, for winding, sinking, haulage, bridge suspensions, aerial ropeways, cranes, elevators, etc.; also running ropes, cargo hauls, standing rigging, etc.; high-grade plough steel steam ploughing ropes and steel-wire rope slings for heavy lifting purposes; specially flexible high-grade tinned plough steel cables and strands for aircraft, etc.; high-grade cotton driving ropes, hemp, manilla, etc.; ropes and cordage for shipping, crane and capstan ropes, manilla and hemp ropes for shipping and fishing industries.

METAL MARKETS

COPPER.—The course of values on the standard market in London during August was fairly steady until about the middle of the month, when an easier tendency was noticeable, and although the last few days of August saw a slight recovery, values showed a loss on balance. The easiness was due to a wave of pessimism which appeared in the market, and it seemed as if certain holders were tiring of their burden. The outlook was—as is still the case—very obscure, and with consumers' demand continuing restricted, the situation presented very little to encourage a bullish view. In the United States there was at one time rather more demand for the metal, but sellers immediately put prices up, according to their usual habit, with the result that the buying movement was scotched, followed by a rapid weakening in values, which was, of course, reflected sympathetically in London. At the moment the best foreign customer of the United States copper producers is Germany, but the recent depreciation of the mark has had a somewhat restraining effect on her purchases. As regards the position in England, manufactured material continues in poor demand, and makers report that the Continent is able to secure a substantial proportion of the available business. It is hoped, however, that the reduction in the price of fuel will assist British manufacturers to compete more advantageously in the near future. The month saw a moderate demand for sheets from India. There has been much talk recently of Germany establishing credits in the United States, and should the scheme succeed it is to be expected that exports of copper to that country might show a certain increase.

Average price of cash standard copper: August, 1921, £68 12s. 8d.; July, 1921, £71 4s. 4d.; August, 1920, £94 1s.; July, 1920, £90 5s. 6d.

TIN.—The standard tin market in London fluctuated within moderate limits during August, but the trend of values was downward until the last few days, when a recovery took place, apparently on speculative buying. In the absence of much genuine consumptive demand, a weak tendency was practically inevitable, and the occasional rallies were due merely to bear covering and other tactics of the professional operators. The general position has thus shown very little change during the month, the large unabsorbed stocks in the East continuing to hang over the market, with an unfavourable effect on sentiment. One reason why the market receives so little support is doubtless the fact that holders find their existing stocks a sufficient burden without adding to them. It is difficult to see any hope of a sustained improve-

ment in values until there is a broadening of consumption, and while the tinplate industry continues depressed this is hardly likely. Continental inquiry has been on the whole disappointing, and demand from the United States, although occasionally stimulated by the falls here, has also been poor. In the Straits sales have been made in fair quantities at about the London parity, and sellers there have evinced quite an eager desire to dispose of metal. Batavia sells occasionally. China, however, has continued to hold aloof. Some hopes are held that the tinplate industry is on the eve of a recovery, owing to the absorption of the war stocks of canned goods and the fact that the relief of the Russian famine will entail the dispatch of vast quantities of tinned meats to the stricken districts.

Average price of cash standard tin: August, 1921, £155 8s. 4d.; July, 1921, £164 13s. 1d.; August, 1920, £274 5s. 10d.; July, 1920, £262 1s. 5d.

Lead.—The London lead market kept remarkably steady during August, and closing values were very little below those at which the month opened. This was due to no small extent to the fact that, unlike most of the other non-ferrous metals, there was quite a fair demand from consumers, which helped to sustain values. This fact is all the more surprising when it is remembered that lead is, relatively, the dearest metal of the four dealt in on the London Metal Exchange. Holders of the metal have not relaxed their firm attitude to any extent, and the spot position has remained tight, aided by irregular shipments and the policy adopted by consumers of buying for prompt delivery only. There is a fairly general opinion that arrivals from Spain are likely to be erratic and restricted for some time to come. On the other hand, reports speak of greater activity at the Mexican smelters, so that supplies from that quarter should be on an increased scale in the near future. It is interesting to notice that the Government has at last disposed of their stocks of lead, estimated at about 10,000 tons. At the beginning of the month there was quite a fair inquiry from the Continent, but later on demand fell away, perhaps owing to American competition there. In the United States the market appears to have a quiet tone, and although the leading producers have made no alteration in their price, lead in bond can be bought at less. News is to hand that the Port Pirie smelter in Australia has resumed operations. The smelter in question was, it will be remembered, recently burnt down, and the reconstructed plant has probably less than half the roasting capacity of the old one, its maximum being about 3,000 tons of concentrates weekly. The actual scale of working will depend almost entirely upon the activities of the Broken Hill mines.

Average price of soft pig lead: August, 1921, £23 5s. 1d.; July, 1921, £23 5s. 10d.; August, 1920, £36 8s. 10d.; July, 1920, £35 9s.

Spelter.—Values in the London spelter market had an easier tendency during the month, despite a slight improvement in the galvanizing trade and a consequent better demand for spelter. The easiness appears to have been due chiefly to the developments in the German situation. The renewed depreciation of the mark led to the natural supposition that exports of spelter from that country might again be feasible on a fair scale. As a matter of fact, a quantity of German spelter has actually been sold here, but there has been no selling pressure from that quarter. Other producing countries have been adopting a rather reserved attitude. Belgium sold a little, and there were offerings of Austrian metal. Norway was a prospective seller at the beginning of the month, but ceased to offer later. The future of the market is largely dependent on whether foreign holders are able to finance their stocks. Consuming demand generally, despite the improvement above referred to, is still none too satisfactory. In America rather a better trade inquiry was reported at the beginning of the month, but this appears to have failed to develop into a serious buying movement, and the position there continues in a deplorable state. Despite the efforts of producers to keep down output, stocks continue to increase, being now more than 90,000 tons.

Average price of spelter : August, 1921, £25 8s. ; July, 1921, £26 12s. ; August, 1920, £41 19s. 6d. ; July, 1920, £42 13s. 3d.

Zinc Dust.—Values have kept very steady. High-grade Australian is priced at £55 per ton, and English and American 92 to 94% about £52 10s.

Antimony.—Prices were unaltered during the month. English regulus ordinary brands, £37 to £40 ; special brands, £38 5s. to £42, and 98% to 99% £29 to £32. Foreign in warehouse is steady at £24 10s. to £25 per ton.

Arsenic.—Business has been very quiet, and producers have reduced the quotation for Cornish white to £32 7s. per ton delivered station London.

Bismuth.—The leading interests continue to ask 7s. 6d. per lb.

Cadmium.—The price has eased to about 5s. 9d. to 6s. per lb.

Aluminium.—Home producers quote £120 for home and £125 for export business, but there has been some foreign material offering below these figures.

Nickel.—The leading producers continue to quote £190 per ton for home and export business.

Cobalt Metal.—The quotation is still 15s. to 16s. per lb.

Cobalt Oxide.—Business is quiet, with black oxide steady at 12s. and grey unaltered at 13s. 6d. per lb.

Platinum and Palladium.—The market has kept steady. Prices are : manufactured platinum £20, raw £17 per oz. ; manufactured palladium £20, raw £15.

Quicksilver.—The trend of prices has been easier, the chief interests having reduced their price, and the present value is about £10 5s. to £10 7s. 6d. per bottle.

Selenium.—Sellers quote 10s. 6d. to 13s. per lb.

Tellurium.—The price is steady at 80s. to 90s. per lb.

Sulphate of Copper.—The quotation is a little firmer at £30 to £32 for home and export.

Manganese Ore.—There has been a rather easier tone, and Indian grades are nominal at 1s. 1½d. per unit c.i.f. U.K.

Tungsten Ore.—Business is dull, with the present quotation for 65% WO_3 at 13s. to 13s. 3d. per unit c.i.f.

Molybdenite.—Sellers quote 37s. 6d. to 42s. 6d. per unit c.i.f.

Chrome Ores.—The price has been steady at £4 10s. c.i.f.

Silver.—The price of spot bars on August 2 was 38⅞d., but Chinese and Indian selling had a depressing influence, and the quotation sagged to 36¼d. on the 9th. Subsequently there was some Indian buying, which carried the price up to 38⅝d. on the 19th. On the 22nd spot bars reacted to 37¾d., only to recover to 38½d. on the 24th. Towards the end of the month there were small fluctuations, the price closing at 37⅞d. on the 31st

Graphite.—Quotations are nominal, business being rather quiet. Madagascar, 80 to 90%, is steady at £20 to £25 per ton c.i.f.

Iron and Steel.—At the end of the month there were fourteen furnaces in operation in the Cleveland district, and four furnaces in Scotland. Pig iron manufacturers have had their attention chiefly riveted upon the course of fuel prices, and are anxiously awaiting the time when pig iron production can be resumed upon an economic basis. Coke is being offered at 35s. delivered, but pig iron makers are not inclined to look at anything above 30s. The official home trade minimum price of No. 3 Cleveland is still 120s., but sellers ask 135s. Export business is quite stagnant. Hematite is a more active market and supplies are scarce, makers not being disposed to resume production on any large scale until fuel is cheaper. Prices are firm at 160s. for the home trade and 150s. for export. British steel has continued under the influence of Continental competition, but German works are filled now for three months ahead. The settlement of the ship joiners' strike here has tended to improve the home position, and orders which were held up on that account and on account of the coal strike are now being placed. An all-round reduction of 20s. was made in home trade steel quotations, but these are still dearer than Continental supplies.

THE MINING DIGEST

A RECORD OF PROGRESS IN MINING, METALLURGY, AND GEOLOGY

In this section we give abstracts of important articles and papers appearing in technical journals and proceedings of societies, together with brief records of other articles and papers; also notices of new books and pamphlets, lists of patents on mining and metallurgical subjects, and abstracts of the yearly reports of mining companies.

THE PRINCIPLES OF COPPER LEACHING

The June *Bulletin* of the Canadian Institute of Mining and Metallurgy contains a paper by Frank E. Lathe, chief chemist of the British America Nickel Corporation, on the "Principles of Leaching and Precipitation of Copper." We reproduce this paper practically in full.

Ten or fifteen years ago hydro-metallurgists were predicting a bright future for leaching processes. Many different methods had been worked out satisfactorily on an experimental scale, and all seemed ready for their commercial application. About that time, however, oil flotation came to the fore, and though not even yet understood thoroughly as far as theory is concerned, it at once proved a great commercial success. In fact, its conspicuous achievements relegated leaching to the background. The chief reason why flotation made such rapid progress in comparison with leaching is that the former fits in well with ordinary gravity concentration, in fact, helps it out where it is weakest, in the treatment of slimes. Leaching, on the other hand, is not well adapted to slime treatment, and involves a separate plant, with new apparatus, new chemistry, and new methods of control. As a result, flotation has advanced more rapidly than leaching, but both have now become so firmly established that the metallurgists who would keep abreast of modern progress must study both carefully. In considering the possibility of leaching a particular ore or tailing, there are important points to be investigated. The present paper is an attempt to answer the questions in the light of the recent success of several large plants.

In Table I will be found a list of the principal leaching plants in operation in America during 1920, with classified information about each. In addition to these, several companies are practising heap-leaching of very low-grade ores on a moderate scale, and many processes are being investigated.

The various operations through which an ore may pass will now be taken up one at a time, and the principal points considered in some detail.

Crushing.—Many factors influence the decision as to the best size for leaching purposes. For heap-leaching, where the operation is expected to require a year or two to go to completion, pieces up to several inches in diameter will be satisfactory. Where ore is leached in tanks, however, overhead expense is considerable, and time becomes an important matter.

Fine crushing possesses the following advantages:

(1) It sets free the copper minerals more perfectly and hence tends to improve the extraction.

(2) It increases the capacity of the plant by shortening the time necessary to dissolve the copper.

(3) If the solvent is sulphuric acid, as is usually the case, less of it will be required. The reason for this is as follows. When coarse pieces of ore are

TABLE I.—PRINCIPAL COPPER LEACHING PLANTS IN AMERICA.

No.	Company	Location	Tons Daily Cap'y.	Material Treated	Gangue	Chief Copper Minerals	Preliminary Treatment	Solvent	Preci-pitant	References

6	Utah Copper	Garfield, Utah	2,000	Ore	Monzonite prophyry	Malachite, azurite	Crushing to half inch	Sulphuric acid	Scrap iron	Rickard, M. & S. P., Dec. 1918.

[illegible] the copper minerals [illegible] this time has [illegible] As the solvent action progresses towards the centre of these pieces it becomes slower and slower, and the acid is meantime [illegible] with the leached outer [illegible] will therefore be neutralized by the basic gangue minerals, while if the ore had been crushed finer the acid would have been drawn off before much of this neutralization had taken place.

(4) It will result in less fouling of the solutions, for the same reason that acid consumption is lowered.

On the other hand, if the ore is crushed unnecessarily fine, there are the following disadvantages:

(1) Considerable expense in crushing will be involved.

(2) Excessive dust will be caused in the crusher building, with consequent injury to the workmen. As a preparation for leaching, crushing is done dry when possible, for reasons which will be apparent later.

(3) The dust losses will be considerable whenever the ore is handled, in the crusher building, on conveyors, and particularly when dropped from loading bridges into leaching tanks. This may appear to be an unimportant detail, but as the fines are usually richest the loss is sometimes sufficient to be seen on the monthly balance-sheet for copper.

(4) Slimes leach poorly, unless they can be agitated, which is not done in any commercial plant yet constructed. Extraction is usually best on fine sands.

(5) Channeling in the tanks may result, so that slimes will interfere with the extraction even on the coarser sizes.

(6) More moisture will be retained after the leaching and washing operations are completed, with consequent loss as water-soluble copper.

Where copper minerals occur mainly in cracks, and joint-planes in the ore, as at Chuquicamata, Ajo, and elsewhere, crushing does not need to be finer than ½ in. in order to give a good extraction. At Lake Linden, on the other hand, the *minus* $\frac{3}{16}$ in. tailing has to be further ground until it will pass a 28-mesh screen. At Anaconda 75 to 80% of the sand tailing being treated will pass 20-mesh, and no further grinding is necessary.

The crushing machinery used in preparing ore for leaching does not differ greatly from that found in ordinary gravity-concentration plants. The horizontal Symons disc crusher is the favourite for intermediate work, while rolls and the vertical Symons are also used to some extent. Vertical Symons and fine rolls reduce to half-inch. At the Calumet and Hecla pebble mills are used for fine grinding.

A device has recently been installed at Chuquicamata for overcoming the dust nuisance in the crusher building. Dust is removed by fans and conducted through pipes to a large wooden settling chamber, from which the collected dust is flushed to the leaching tanks.

De-sliming.—If ½ in. ore is being leached, no de-sliming is required before sulphuric acid leaching. The Anaconda plant treats a tailing which contains no great amount of slime, hence percolation is good. The feed is partially de-slimed at Kennecott, and more completely at Lake Linden, where *minus* 200-mesh material is carried off in the overflow from V-shaped settling tanks. Such slimes cannot be leached well without agitation, but may be treated by flotation.

Roasting.—On account of the expense, this step will of course be omitted if possible, and many operators of the present day would say that the necessity of roasting an ore debarred leaching processes altogether. This conclusion is by no means justified. The Anaconda Company roasts tailing with 3·3% of coal, and makes a profit when handling material as low as 0·5% copper. That being the case, there is no reason why leaching should be considered out of the question simply because the copper minerals in the ore are not soluble in sulphuric acid.

When roasting is used as a preparation for leaching, the combined process will in many instances become a serious competitor of flotation. Roasting and leaching have even been made the subject of large-scale experiments on such material as flotation or other concentrates, and it is claimed that these mixed sulphides may be roasted to make soluble 95% of the copper and not more than 1% of iron, in which case electrolytic precipitation should be possible.

The chief objects of roasting are to increase the solubility of the copper and decrease that of the gangue. Copper sulphides are almost insoluble in ordinary leaching solutions, while those of iron are often fairly soluble. In a general way the opposite is true of the oxides. Roasting therefore brings about these two desirable ends, and in addition agglomerates the fine particles so that percolation takes place more readily. In some cases certain impurities like arsenic and antimony are partially volatilized at the same time.

Free access of air is of course necessary for oxidation. In addition to this, temperature control is important. At a low heat sulphates are formed of both copper and iron, and the most desirable temperature is one at which the latter readily breaks up into sulphur trioxide and iron oxide, but at which the copper sulphate is not decomposed. This is about 550° C. Laist states that if the temperature rises too high some of the copper will become insoluble in all acids except hydrofluoric. This will not take place, however, until the temperature is higher than that necessary to decompose copper sulphate, which is 650–700° C. If the heat is sufficient to sinter the sulphides, the copper is likely to be found partly as undecomposed sulphide, half fused, and partly as oxide, but not at all as sulphate, which is the most desirable form if acid consumption is to be kept down.

Chemicals are sometimes added, either to the charge or to the roasted product. Of these the most common is ordinary salt, the presence of which renders much of the copper soluble in chloride solutions, even in the absence of acid, and is especially useful in converting silver and gold into chlorides, in which form they also are readily soluble. In addition, the presence of salt increases the oxidizing action of the air. When leaching was first begun at Anaconda, about 1·5% of salt was added after the roasting operation was complete to increase the extraction of silver, but its use was discontinued some two years ago, chiefly on account of the increased cost of salt delivered at Anaconda.

As Anaconda has the only large-scale plant roasting ore or tailing as a preparation for leaching, a brief description of that plant may be of interest. Roasting is carried out in six-hearth modified McDougall furnaces, 20 ft. in diameter, and fired with coal on the third hearth. The temperature of this hottest hearth is about 535° C., control being

made easy by means of a series of recording pyrometers. Sulphur in the feed is a little over 2%, and this is reduced to about ½%, a part of which is present in the roasted material as soluble sulphates. Each furnace has a capacity of about 75 tons in 24 hours. As already mentioned above, the coal consumption is only about 3·3%, a part of the heat required being furnished by the oxidation of sulphur and iron.

Solvents.—The ideal solvent would be cheap, easy of transportation, or capable of being manufactured at the plant where used, non-volatile, and easily recoverable from its solutions with accompanying precipitation of the copper in a marketable form. Also, when considered in relation to a particular ore, it should completely dissolve the copper without attacking the gangue.

The standard works on leaching give lists of many solvents, including water, sulphuric acid and sulphates of various metals, hydrochloric acid and many chlorides, ammonia, and ammonium salts, sulphurous acid, nitric acid, and others. None of these comes near to the ideal solvent, and most of them are so far away from it that it is unlikely that they will ever be used in commercial operations on a large scale.

Of the solvents named, sulphuric acid is the best, and about 75% of all leaching at the present time involves its use. It has the advantages that :—

(1) It is the cheapest of all solvents except water.

(2) It can frequently be manufactured at the plant where it is to be used, perhaps utilizing for the purpose waste gases from roasting operations.

(3) It is easily regenerated by electrolysis of the copper-bearing solutions.

(4) The copper recovered is of very high purity, and needs only to go through the ordinary furnace-refining given to all high-grade copper in order to make it suitable for wire-bars.

(5) It is non-volatile, and therefore easily handled.

Sulphuric acid, however, possesses some disadvantages which entirely prevent its use in some instances. For example :—

(1) It does not dissolve metallic copper.

(2) It dissolves only half the copper from cuprite, leaving the remainder in the form of metal.

(3) It readily attacks carbonates of lime and iron, which are frequently present in the gangue of copper ores, causing both a heavy consumption of acid and a contamination of the solutions.

(4) It has some action on oxides and silicates of iron and aluminium, which cause trouble by fouling the solutions.

Ammonia, or ammonium carbonate, is being used at the two modern plants, the Calumet and Hecla and the Kennecott, and it is therefore worth while examining its suitability as a solvent. On the one hand : (1) It is expensive. (2) It is not possible to regenerate it by electrolysis of the solutions. (3) The copper recovered from ammoniacal solutions requires further treatment. (4) It is volatile, and therefore difficult to handle. These disadvantages show that ammonia cannot hope to compete with sulphuric acid in the field where the latter is suitable. But ammonia, on the other hand : (1) Dissolves metallic copper readily. (2) Completely dissolves cuprite. (3) Does not attack carbonates of lime or iron. (4) Does not attack compounds of ferric iron or alumina. (5) Is very perfectly recovered by distillation, fouling of solutions being therefore impossible.

Ammonia, therefore, fills just the field in which sulphuric acid is useless. This is well illustrated by a consideration of the two plants using ammonia leaching processes. At the Calumet and Hecla, where native copper is dissolved from mill tailing, sulphuric acid could not be used because of its lack of action on the copper. At the Kennecott plant, where copper carbonates occur in dolomitic limestone, sulphuric acid would dissolve the copper readily, and decompose the gangue almost equally well.

Sulphurous acid, that is, an aqueous solution of sulphur dioxide, has been made the subject of a great number of experiments, and it is possible that it may yet be used on a considerable scale, with precipitation of copper by scrap iron or otherwise. In the majority of cases, however, it will pay better to oxidize it to sulphuric acid, which will make possible the electrolysis of solutions and obviate the difficulty arising from fumes.

Ferric salts are good solvents for oxidized or metallic copper, and even for chalcocite. One of the chief advantages of their use is that they do not ordinarily attack the gangue. Difficulties are that where ferric salts are reduced in the process their complete oxidation is not easily brought about, and that precipitation by electrolysis is not possible. Ferric sulphate is used chiefly in heap leaching, with precipitation on scrap iron.

None of the other solvents is of sufficient importance to make its consideration desirable in a brief review like the present.

From the foregoing it will be evident that so far as present practice is concerned sulphuric acid and ammonia have the field very much to themselves. While the others are not likely to be applied on a large scale in the near future it must not be forgotten that even ten years ago a commercial ammonia process seemed very far away.

Sulphuric Acid Process.—Where fine and comparatively uniform material is to be leached no particular attention need be paid to the distribution of the charge in the tanks. This is the case at Anaconda. But when the ore contains pieces varying in size from nearly an inch in diameter to the finest of slime, precautions have to be taken to prevent channels of coarse ore through which an excessive amount of solution might pass, to the detriment of the remainder of the charge. The large tanks are usually rectangular, and are spanned by loading bridges on which run conveyor belts carrying the ore. A moving tripper distributes it uniformly over the full width of the tank. The tanks are usually 10 to 15 ft. in depth, and it is best to make the layer of ore in the tank the full depth in one trip. The coarser material falls to the bottom, so that there is a certain amount of stratification, but this is desirable rather than otherwise. In filling the final end of the tank it is wise to go only so far that the bottom of the ore slope comes near the end wall, and then move the distributor so that the ore falls directly against the wall, going backwards to fill the remaining space. Otherwise there would be a column of the coarser ore against the end, which it is desired to prevent.

It has been suggested that the best method is to charge the ore with solution already in the tank. When tried on a large scale, however, it is found that this practice results in too much classification, and that percolation and solution of the copper are both slower.

There is no part of the leaching process which is more confusing to one not accustomed to it than

the circulation of solutions. Moreover, each plant has its own system, so that it is almost impossible to generalize. For the purposes of this paper the author decided to choose as an illustration the practice that appears to him most rational and of most general application, namely, that of the Chile Exploration Co., at Chuquicamata. The writer distinguishes the various solutions by letters, taken alphabetically in the order in which they are used, from A to F. Thus A is that going from the leaching plant to be purified on its way to the electrolytic tanks, B and C are the two leach solutions put on the ore, and D, E, and F the three wash solutions, to be followed by fresh water. It should be mentioned here that each of these has its own solution tank in which it is stored while not being used on any ore tank, and these solution tanks will be designated by the same letters as the solutions themselves. The solution analyses to be given are only approximate, as they vary considerably. Table II is an illustration of the working of the system to be described.

TABLE II.—LEACHING CYCLE AT CHUQUICAMATA.

Solution.	Cubic Metres On.	Cubic Metres Off.	Solution.
Moisture	100		
B	3,200 }	3,800	A
D	600 }		
C	3,200	3,200	B
D	2,600	3,200	D
E	3,200	3,200	E
F	2,500	2,500	F
Water	1,400	900	(in tailing)
	16,800	16,800	

The first solution put on a fresh tank of ore is B, only moderately high in both copper and acid (Cu, 25 grammes per litre; H_2SO_4, 45 g.p.l.). This is admitted from the bottom, in order to keep the slimes as far away from the filter as possible, and in amount just sufficient to cover the ore well. It is left on the tank from four to eight hours, depending on the requirements of the electrolytic tank-house, and is then drawn off as A (Cu, 55 g.p.l.; H_2SO_4, 20 g.p.l.). As soon as the withdrawal of A is begun it is followed on the tank by some of D, the first wash (Cu, 15 g.p.l.; H_2SO_4, 28 g.p.l.), the amount varying with the estimated grade of the ore charged.

All the solution being drawn off is sent to the A tank until it is down to 30 g.p.l., so that the volume is greater than that of B put on, greater, if the estimate has been correct, by the volume of D used.

After the small volume of D has been added it is followed by a large volume of C (Cu, 13 g.p.l.; H_2SO_4, 80 g.p.l.), which is the spent electrolyte from the tank-house. This strongly acid solution does the most difficult part of the leaching, and is therefore left on the ore for as long as possible, usually about 36 hours. At the end of that time it is withdrawn, becoming the new B solution, and is at the same time followed by wash solution, first the remainder of D, then E (Cu, 8 g.p.l.; H_2SO_4, 12 g.p.l.), F (Cu, 4 g.p.l.; H_2SO_4, 5 g.p.l.), and clean wash water, in rapid succession. In drawing off these solutions the division between them is not made as in the first case, by copper analysis, but by volume, so that the remainder of D, with a small part of E, goes into the D tank, the remainder of E, with a small part of F, into the E tank, and the remainder of F, with all the wash water, into the F tank.

The amount of wash water which can be used is in the long run the sum of the solution discarded in the electrolytic tank-house, evaporated in the circuit and left in the tailing as moisture, less, of course, the original moisture in the ore. At Chuquicamata the last item is very small, but it is worth mentioning because it illustrates why the ore should not be sprinkled to keep down the dust in the crushing plant. In order to keep the water-soluble copper below 0·01% it is necessary to use about 1,300 tons of water per 10,000 ton tank. After washing, a tank is drained 12 to 24 hours, the longer time being especially necessary when but little wash water has been used.

It is not possible to compare methods in use at different plants with perfect fairness unless all the conditions are carefully considered, which is not possible in this paper. However, some points regarding the practice at Ajo may be mentioned here, and Ajo is more nearly comparable than any of the other plants because it also uses electrolytic precipitation of the copper.

At Ajo the acid in the solutions is run much lower, on account of the much greater solubility of the gangue. The first solution on fresh ore in a tank is circulated through that tank until almost neutral. When drawn off it is followed by several leach solutions, with gradually increasing acid, until at the end of a week the acid has risen to 30 g.p.l. In their practice it has been found that the maximum extraction per pound of acid consumed is given by this long treatment with weak solutions, although of course a larger plant is required. The strongest acid solution is followed by the first of four washes. Each of these is circulated on itself for three hours, until the soluble copper remaining in the ore is uniformly distributed through it, and the tank is then drained before the next wash solution is admitted. The water-soluble copper remaining in the tailing is about 0·06% out of a total of 0·28.

Comparing the two systems, the percolation at Chuquicamata is downward except for the first solution, that at Ajo is altogether upward. The Ajo metallurgists state that upward percolation reduces channeling and effects a more rapid extraction of the copper. On the other hand, their method results in ten times as much water-soluble copper in the tailing, which means a loss of two or three tons of metallic copper per tank. The efficiency of the Chuquicamata method is due to the fact that each succeeding wash put on is lower in specific gravity than the previous one, and there is very little mixing of solutions. To one familiar only with the chemical operations of a laboratory the difficulty of mixing solutions of different specific gravity in large tanks is almost incredible In fact, the theory has been advanced in all seriousness that a uniform solution if left undisturbed for some time will tend to stratify, which is the opposite of the teachings of textbooks. The draining method is doomed to inefficiency because of the considerable amount of each solution remaining in the ore when drained. This can at best only be diluted by the succeeding solution. Downward percolation has the additional advantages that it greatly lessens the amount of slime carried over to the solution tanks, and requires

less power, as the solutions find their way down through the ore by gravity. If, however, the ore in the tank be wet at the beginning of the leaching operation it is desirable to admit the first solution from the bottom, in order to make the water rise ahead of it and go to waste until traces of copper appear. As mentioned above, it is for another reason that it is admitted at the bottom at Chuquicamata, namely, to keep the slimes away from the filter.

As for the advantage of continuous percolation over merely allowing the solutions to stand on the ore, this must be determined for each separate plant. In general, low-grade ore does not require continuous percolation, but it may be essential for ore of high grade. The reason seems to be that with richer material it is necessary to circulate in order to bring a sufficient amount of acid in contact with the copper minerals to effect their solution. In such a case continuous percolation has been known to raise the extraction as much as 30 per cent.

An extension of the time of leaching will usually result in better extraction, or, if the acid concentration of the leach solutions be reduced, in a lower acid consumption with equally good extraction. In normal times the saving thus obtained must be balanced against the cost of additional plant required for an extension of the leaching period. During curtailed production, however, the time may be lengthened to great advantage. Thus at Chuquicamata the average extraction for February, 1921, was raised from the normal of 90–92% to 94·15%. A 40% curtailment at Ajo in March, 1919, reduced the acid neutralized per ton of charge from 67·4 to 45.

The percentage of the total copper which can be extracted in leaching will vary considerably, as some copper is nearly always present as sulphide or in some other insoluble form, and all that the leaching plant should be asked to do is to dissolve a satisfactory percentage of the copper which is soluble in sulphuric aid. The percentage of the acid-soluble copper which is dissolved ought not to be under 85 per cent.

Leaching tanks in the larger plants using sulphuric acid as solvent are usually made of reinforced concrete, with a lining of either lead or mastic asphalt. The lead may be protected from mechanical wear by wood. The smaller tanks, of circular form, are more often of wood, with lead linings. Tanks are emptied by several methods: at Garfield and Chuquicamata by Mead-Morrison unloading bridges, which span the tanks, at Ajo by Hulett unloaders, and at Anaconda by flushing out with water. All these methods are proving satisfactory.

Leaching for precipitation on iron does not differ radically from that just given. The chief differences are caused by the fact that one does not have to plan for the recovery of the acid, which is all lost, and that the fouling of solutions is important only in so far as it increases the consumption of acid. To avoid a large consumption of iron and sulphuric acid the solution going to the precipitation plant should be very low in free acid, which attacks iron readily. It is therefore kept on fresh ore long enough to become practically neutralized. Ferric salts also have a solvent action on the iron, but these are not usually present in large amount. At Garfield the general scheme is not unlike that at Chuquicamata, though there is more circulation of the solutions in the tanks by means of a series of air-lifts.

At Anaconda, where precipitation on iron is used and all acid is lost, this loss amounts to about 65 pounds of 60° acid per ton of tailing. At Ajo much of the acid is regenerated in the electrolytic deposition of the copper, as well as in the purification of the solutions by sulphur dioxide, but the acid consumption is some 90 pounds per ton of ore, the larger amount being due to the relatively greater solubility of the gangue. At Chuquicamata there is a very considerable amount of combined sulphuric acid in the ore, so that if no solutions were discarded in the tank-house there would actually be an increase of acid in the system. As it is, the new acid required amounts to only four or five pounds per ton.

Purification of Sulphate Solutions.—Purification is not necessary except as a preparation for electrolysis, for owing to the discarding of all solutions in precipitation on iron there is no cyclic increase of impurities.

Any gangue material soluble in sulphuric acid is liable to increase to the point of saturation. This may do no harm, if it be chemically inert like calcium sulphate; it may not be within commercial control except by discarding a part of the solution, as, for example, nitric acid; or it may be capable of reduction by a comparatively cheap means, as in the case of ferric iron and chlorine.

Ferric iron is the *bête noire* which haunts the copper hydro-metallurgist in his dreams, and turns his hair white before its time. It is mainly responsible for the difficulties of electrolytic work, and has probably caused more failures than all other impurities combined.

It is possible to entirely remove ferric iron from the solution by precipitation with copper oxide, this being produced especially for the purpose or obtained from the ore itself. In the latter case the difficulty is that in order to dissolve the copper completely it is necessary to follow the purified solution with an acid one, which picks up the precipitated ferric oxide for another trip on the merry-go-round. Fortunately iron in the ferrous condition is almost harmless, so the efforts of the metallurgist are usually directed towards methods of reducing it to the ferrous condition instead of eliminating it from the system.

At Ajo the reduction is made by means of sulphur dioxide. This does not act well in a strongly acid solution, so the solution used in the leaching process, as noted above, is made almost neutral before being sent to the reducing towers. It passes through the towers which are filled with a wooden checkerwork, counter-current to the flow of sulphur dioxide produced in roasting pyrite, and a very good absorption is secured. While being reduced to the ferrous condition ferric iron oxidizes sulphur dioxide to sulphuric acid, which is an important gain.

The reduction brought about in the towers brings the ferric iron down from 10 to 2·5 g.p.l. and increases the acid from 4·0 to 16 g.p.l. This is done without saturating the solution with sulphur dioxide to such an extent that it gives much trouble in the tank-house, although it is well to provide for good ventilation where their gas is used.

It was also suggested at Ajo to utilize the cement copper produced in the precipitation-on-iron plant to reduce the ferric iron of the solutions. This was tried and proved successful, but it usually pays to ship the cement copper and use sulphur dioxide reduction.

Chlorine is present in the Chuquicamata ore,

[illegible] agitating the solution with fine cement copper, which at the same time reduces much of the ferric iron present. The cuprous chloride is dissolved in a ferrous chloride solution and then the copper is precipitated on scrap iron, most of the cement copper so formed going back to the dechloridizing plant.

[illegible] This is perhaps the most difficult part of the hydrometallurgy of copper. If the solutions contained nothing but copper and sulphuric acid the operation would be an easy one, but impurities cause no end of trouble, which can be overcome only by persistent effort.

Many different materials have been suggested for the anodes, but only four have been used to any extent.

Graphite, or carbon in some other form, has many strong advocates, but so far has been practically limited to chloride solutions. If used for sulphate solutions the oxygen liberated at the anode will attack it vigorously unless neutralized by some reducing agent like sulphur dioxide. Ferric salts are also extremely corrosive to carbon. But the voltage used is low, and the amount of acid regenerated is very high, so there are great inducements for further experimentation. It is not at all unlikely that it will be used on a large scale when the various difficulties have been overcome.

Lead containing up to 10% of antimony is very satisfactory for pure sulphate solutions, owing to the insolubility of lead sulphate. Even ferric iron has no effect on it. If much chlorine is present, however, these anodes go to pieces rapidly, and their solution is even more rapid with nitric acid in the electrolyte as at Chuquicamata The only trial they have had on a large scale is at Ajo, and there they are giving splendid service. At the end of the first year of operation they were almost as good as new, so it is certain that anode replacement will be a small item.

Chuquicamata, with sulphuric, nitric, and hydrochloric acids in the solutions, has had the most difficult problem. Here both magnetite and ferro-silicon have been used. In the early experimental work it was decided to use fused magnetite anodes made in Germany, and these were installed in the large plant. Then the breaking out of the European war prevented the shipment of a further supply, and ferro-silicon (about 13% Si) was substituted for magnetite. This was much inferior to magnetite chemically, but far better in its mechanical and electrical properties, and cheaper. The war has been over more than two years, but ferrous-silicon anodes are still in use. The company's research laboratory has developed several promising new materials, and may yet be rewarded by an anode which will be a success commercially. The difficulties with ferro-silicon are that it is not entirely insoluble in the solutions used, so that anodes of this material have to be replaced from time to time, and that the iron dissolving contaminates the solution. In fact, the necessity of discarding a large quantity of solution at that plant is due entirely to the solubility of the anodes, for the tailing contains as much iron as the ore itself. Some solution would have to be discarded, in any case, to eliminate the nitric acid, but that does not do so much harm when the ferric iron is low.

The electrolyte employed differs from the electrolyte used in ordinary copper-refining chiefly in the lower acid content and higher impurities. The former is due to the effort to avoid acid consumption by action on the gangue, which would be increased by high acid in the solutions. At Ajo it is further lowered to gain efficiency in the reduction of ferric iron by sulphur dioxide. In order to increase the acid and lower the copper at Chuquicamata the solution from the dechloridizing plant is diluted, before going to the tanks, with some of the solution which has been partly electrolysed and therefore has had a part of its acid regenerated.

The impurities in the electrolyte are those which have not been eliminated by some process of purification of the leaching plant solutions. Ferric iron in the head-tank solution is usually low, because it can be controlled, but the ferrous iron may be high, and this is a latent source of trouble on account of the ease with which it is oxidized. As the total iron increases, the trouble with ferric iron becomes so great that something radical has to be done, and this usually means discarding the solution after removal of the copper. Ferric iron has a very considerable solvent action on the copper deposited, thereby lowering the ampere efficiency and also increasing the voltage. Chlorine up to 0·5 g.p.l. has no great effect on the current efficiency, and a considerable part of it is deposited with the copper; chemically deposited, because electrically it would go to the anode. The small amount of chlorine which may be introduced into solutions in the wash water used has not been found harmful to lead anodes, as was feared before they were given a commercial trial. At Ajo about two-thirds of the chlorine is deposited with each cycle through the tanks. Nitric acid may run up to 15 g.p.l. without doing any serious harm, especially if the ferric iron is low, but at high concentration or in a warm electrolyte it attacks both cathode and anode, at the same time giving off obnoxious fumes in the tank-house.

On account of the high voltage necessary to deposit copper with insoluble anodes, it is not necessary to heat the solutions. In ordinary copper-refining this is done to decrease the ohmic resistance of the electrolyte, but when ferric iron is present it is desirable to have the temperature as low as possible to avoid the solvent action of these impurities on the deposited copper. At Ajo the temperature of the solutions remains about 30° F. above that of the atmosphere, but at Chuquicamata, where the current density and the resistivity of the anode are both higher, the heating is great enough to make necessary a cooling tower through which the electrolyte goes.

In discarding solution from the tank-house to eliminate impurities, the copper may be removed by electrolysis, or by precipitation on iron, or by a combination of these methods. The choice depends chiefly upon the relative cost of electric current and scrap iron, and the means at hand for disposing of the impure electrolytic or cement copper produced. Electrolysis is done at the cost of a greatly reduced current efficiency, while conditions are also bad for precipitation on iron, on account of the acidity of the spent electrolyte. At Chuquicamata electrolysis alone is used, and the impure (arsenical) copper is sent to the anode furnace making soluble anodes for the starting-sheet section of the tank-

house. At Ajo the spent electrolyte is passed over scrap iron, and the cement copper is shipped or used to reduce ferric iron in the solution.

The spent electrolyte may not, however, always be the proper solution to discard. It may be that in the leaching process iron and alumina will actually be precipitated on the ore, only to be picked up again by the strong acid and wash solutions. If as a result the wash solutions contain more iron and less free acid in proportion to the copper content than does the spent electrolyte they can be discarded to advantage. It will mean less copper to precipitate per unit of iron discarded, and less acid lost as well. Also, on account of the lower acidity, the consumption of scrap iron should not be as high as when precipitating copper from spent electrolyte. In addition, the water-soluble copper in the tailing can be kept down by using an extra amount of wash water and then passing this over scrap iron.

The theoretical voltage necessary to decompose copper sulphate with an insoluble anode is 1·22. In practice nothing near this is ever reached, owing chiefly to the solvent action of impurities, but all the factors ordinarily met with in copper refining also play a part. At Ajo, where the current density is low (7·5 amperes per square foot) the voltage is just over two; at Chuquicamata, with anodes of greater resistivity and nearly double the current density, it is about 2·8. The current density should be about that used in ordinary refining under similar cost conditions. A higher current density has been advocated in order to more perfectly overcome the solvent action on the cathodes, but this does not take into account the heating of the solutions with the higher current, which will cause the solvent action to increase in even greater proportion than the amperage.

The current efficiency in a new plant is usually low, not so much on account of difficulties inherent in the process as because it is necessary to start with a green crew. When men have been properly trained for the work it is not unreasonable to look for an efficiency of 80 to 85%. The amount of copper deposited per kilowatt-hour should be 0·7 to 0·9 lb.

The starting-sheet section may be practically the ordinary starting-sheet department of a copper refinery, when soluble anodes are used, as at Chuquicamata, or the starting sheets may be made from the usual tank-house solution, with insoluble anodes, as at Ajo. If the anodes can be provided without too great expense, it will be found advantageous, in most cases, to adopt the former system, owing to the better quality of the sheets produced.

Percipitation on Iron.—This method will usually be adopted in small plants where it is desired to keep the initial expense of construction down to a minimum, and in large-scale operations as well when iron can be obtained as a by-product of the company's shops, as at Anaconda and Garfield. These plants are also favoured by having a ready means of disposing of the cement copper produced. The installation of electrolytic tank-houses should be undertaken only by companies with the best of metallurgical skill at their command.

Precipitation may be done with almost any kind of scrap iron, old tin cans, and old galvanized iron utensils being used in large quantities for the purpose. Sponge iron, that is, iron reduced from its ores at a low temperature, and consequently very porous, would be almost ideal as an iron precipitant, but its production on a commercial scale has not been a part of the practice of any of the large companies. Both the Anaconda and New Cornelia (Ajo) have done extensive experimentation along this line, and it is believed that the difficulties encountered are not insurmountable.

Precipitation formerly took place in launders, which required a fairly large plant and involved difficulties in handling materials. Now, however, the tendency is to precipitate the greater part of the copper in modified tube-mills filled with scrap iron, through which the solution flows on its way to the launders for the final precipitation. This centralizes the handling of both the scrap iron and cement copper, for which machinery can then be used to advantage. The Utah Copper Co., at Garfield, has the most extensive installation of this kind, though it has been practised for some years at Chuquicamata in the recovery of copper from the cuprous chloride.

Theoretically the consumption of iron in the precipitation of copper from cupric solutions is nine-tenths of a pound per pound of copper, and half of that amount from cuprous solutions. Owing, however, to the action of acid and ferric salts, these figures cannot be even closely approached in practice. Twice the theoretical consumption would be more nearly normal in sulphate solutions, with better than that in chloride solutions.

The cement copper is always contaminated with iron and other impurities, so that it will not usually analyse higher than 65 or 70% copper.

Ammonia Leaching.—The success of ammonia leaching may be ascribed chiefly to the overcoming of mechanical difficulties in handling a solvent so volatile, so that the mechanical features of such a plant are specially important. Steel tanks are used by both the Calumet and Hecla and the Kennecott, but these differ considerably in detail. In the former each tank has a removable cover, which is taken off for charging and other operations, while the solution is not on the charge. At Kennecott the covers are dome shaped, and riveted to the tanks, and are made sufficiently strong to withstand an internal pressure of 10 lb. to the square inch. Manholes are provided, as also are others for charging and manipulating the feed distributor and excavator, which are permanent fixtures inside the tanks. The reason for the Kennecott construction is that the washing of the tailing is done with steam under pressure, the system being patented by them. Covered tanks are provided in both places for solution storage.

The chemistry of the operation is simple. At Lake Linden ammonium carbonate is bought, and this, with the oxygen of the air, acts on the metallic copper as follows :—

$$2(NH_4)_2CO_3 + O_2 + 2Cu = 2CuCO_3(NH_3)_2 + 2H_2O$$

This cupric-ammonium carbonate has a solvent action on more copper, producing cuprous-ammonium carbonate :—

$$CuCO_3(NH_3)_2 + Cu = Cu_2CO_3(NH_3)_2.$$

This again is oxidized by the air to cupric-ammonium carbonate :—

$$2Cu_2CO_3(NH_3)_2 + O_2 + 2(NH_4)_2CO_3 = 4CuCO_3(NH_3)_2 + 2H_2O.$$

In this way the air really furnishes all the oxygen required, and the ammonium carbonate and cupric-ammonium carbonate simply act as carriers for it. In plant operation this oxygen is introduced by passing air through the first and second leach

solutions, which have their copper thus converted to the cuprous condition. Any ammonia gas which is carried off during the operation is absorbed in water.

At Kennecott, where the ore is a carbonate, the solution is bought as ammonia, but this is of course rapidly converted into the carbonate. In both plants the ammonia and the carbon dioxide combined with it are recovered by distillation, the compounds being broken up by heat, but again re-forming in the condensers, while copper oxide is precipitated in the residual solution.

The leaching cycle is not radically different from that used in sulphuric-acid leaching, and the same precautions should be observed, except that in this case there is no fouling of solutions to worry about. At Lake Linden two leach and two wash solutions are used, followed by wash water, the quantity of the latter being dependent upon the volume sent to the stills. This will naturally be kept at as low a point as possible, as the cost of steam for distillation is one of the principal items of expense. In washing at Kennecott, steam is introduced at the top, and passes through the charge, being thus preceded by a wash of condensed steam. The ammonia is thus driven out by volatilization. The amount of steam necessary per ton of charge is about 100 lb. at 5 lb. pressure, and some 20 hours are required for the operation.

Theoretically all the ammonia should be recovered. In practice there is lost about one pound per ton at Lake Linden and half that amount at Kennecott. The better recovery at the latter place is due to the steam wash, but it is doubtful whether in the average plant it would pay for the cost of steam consumed. Steam and ammonia account for about 60% of the total cost at both plants. The stills consist of a series of cylinders placed vertically, the copper ammonia solutions passing down while steam ascends. The first cylinders remove nearly all the ammonia, and the second series complete the operation. At first much trouble was experienced owing to the precipitated copper oxide adhering to the stills, but this was overcome by placing in each a revolving scraper to remove it as fast as formed.

The leaching plant at Lake Linden made last year about 11,000,000 lb. of copper, which cost less than six cents a pound up to smelting. The recovery was over 80%. At Kennecott the recovery of oxidized copper was about the same, the cost per ton of tailing somewhat higher and that per pound of copper a little lower, owing to the higher grade of material treated.

Selection of Leaching Processes.—The characteristics of an ore suitable for leaching by one of the methods described are :—

(1) The copper minerals must be soluble in sulphuric acid or ammonia, or capable of being made so by a cheap method, as roasting. This applies to nearly all ores except possibly heavy sulphides.

(2) The gangue minerals must be nearly insoluble in either acid or ammonia, or capable of being made so. This also applies to most ores.

(3) Gold and silver should either not be present in appreciable quantities or should be rendered soluble by a chloridizing roast or leach. It should be mentioned that there is no large-scale plant recovering both copper and precious metals in this way, but such may be expected as a result of future developments.

On account of the strong competition of flotation in handling sulphide ores, the most promising extension of leaching in the near future would seem to be the treatment of the large bodies of partly oxidized ores at present lying idle. These will, of course, require a preliminary roast. And the day may not be far distant when a roasting and leaching process producing electrolytic copper may be found preferable to the usual combination of gravity concentration, flotation, smelting, converting, and electrolytic refining, even on ores which are well adapted to flotation.

Leaching has been applied in the past almost entirely to low-grade material, but this limitation is not imposed by the nature of the process. If it be commercially feasible to roast and leach the tailing from a gravity-concentration plant, it may be even more profitable to similarly treat the ore itself.

When viewed in the light of its financial success, leaching makes an excellent showing. In fact, the profits made by companies handling low-grade ore or tailing are an indication that under suitable conditions leaching costs compare favourably with those of any methods of treatment yet devised.

DRESSING OF WOLFRAM ORES IN QUEENSLAND

Reference was made recently in the MAGAZINE to the mines and dressing plant of the Burma Queensland Corporation, at Wolfram Camp, North Queensland. A detailed description of the mill is given in a paper by W. H. Bowater, showing how the tungsten, bismuth, and molybdenum minerals are separated, appearing in the *Proceedings* of the Australian Institute of Mining and Metallurgy, No. 40, 1920.

A commencement was made with the erection of the first unit of the new mill in August, 1917, and milling and concentrating commenced in February, 1919. The ore is essentially quartz, the richer values occurring in lumps and patches in this quartz. Between the quartz and the granite there is a transition zone, through which the molybdenite is more evenly distributed. The chief minerals are molybdenite, wolfram, metallic bismuth, bismuth sulphide, bismuth carbonate, and, rarely, a little scheelite. The wolfram is of a very friable nature, and, as the quartz gangue contains the molybdenite, a screen must be chosen so that the wolfram is slimed as little as possible and at the same time the quartz reduced as much as possible.

The ore from the company's various mines is delivered by the aerial ropeway into the off-loading bin (see Fig. 1), passing from this bin over No. 1 grizzly with 2 in. openings. The oversize from No. 1 grizzly passes to No. 1 jaw crusher, set to break at 2·5 in., and thence to No. 2 grizzly with 1·5 in. openings. The oversize from No. 2 grizzly passes to No. 2 jaw crusher, set to break at 1·5 in., then joins up with the fines from No. 1 grizzly and No. 2 grizzly, the whole then passing to the intermediate bin. From the intermediate bin the ore is trammed to the battery bins, side-tipping trucks of one-ton capacity being used. The ore is distributed as required for each 5 heads of stamps. At the

Flow-sheet of Burma Queensland Corporation's Mill.

time of writing the first unit of 20 heads of stamps was in commission, arranged in groups of 5 to each box. From the battery bins the ore is automatically fed through Challenge ore-feeders to the stamp boxes. Stamps are of 1,250 lb., run at 100 drops per minute, with from 6 in. to 7 in. drop. The depth of overflow is approximately 10 in. Woven wire screens are used with apertures of 1/10 in. to 1/12 in., the latter for ore richer in molybdenite. The stamp duty varies from 5·5 to 5·8 tons per head per 24 hours. The mortar boxes are set on concrete foundations with a ⅝ in. rubber sheet between the box and concrete. The pulp, passing from the stamper boxes, is automatically sampled before passing to hydraulic classifiers (No. 1 group), one classifier for each 5 heads of stamps. The spigot (⅝ in. diameter) from each classifier passes to its settler (B), the overflow from each classifier joining up and passing to settler (C), the overflow of settler (C) being divided and passing to two settlers (CA). The spigot (½ in. diameter) from each settler (B) passes to Wilfley and Buss tables, one table to each settler. The overflow from settlers (B) joins up and passes to a large settler (D), the spigot (⅝ in. diameter) of which passes to a Wilfley table. The overflow of settler (D) passes to a still larger settler (E), the spigot (⅝ in. diameter) of which is sent to classifier No. 2 group, the overflow being sent to the tailings launder of the group of Wilfley and Buss tables, assisting to flush out this launder. Three products are made on the concentrating tables: bismuth-wolfram concentrates, middlings, and tailings. The bismuth-wolfram concentrates assay 30% to 45% WO_3 and 5% to 7% Bi. The middlings assay approximately 8% to 10% WO_3 and 5% MoS_2, and contain a fair percentage of pyrites. The tailings contain 0·1% to 0·13% WO_3, the percentage of MoS_2 varying, depending on the degree of fineness of stamping.

The concentrates are sent to the drying and magnetic separation room.

The middlings pass to Wheeler pans, thence to

[illegible] classifiers No. 2 group. The spigot of these classifiers ([illegible] in. diameter) pass to Krupp tables, producing bismuth-wolfram concentrates, middlings, and tailings. The bismuth-wolfram concentrates assay 25% to 40% WO_3 and 3% to 5% Bi, and are sent to the drying and magnetic separation room. The middlings from the Krupp tables are elevated back to the Wilfley table dealing with the spigot from settler (D). The overflow from each classifier joins up and passes to a settler (F). The spigot (½ in. diameter) of this settler passes to an Isbell vanner, producing bismuth-wolfram concentrates and tailings. The concentrates, containing 15% to 25% WO_3 and 3% to 4% Bi, are sent to the drying and magnetic separation room. The overflow passes to two settlers (G). The spigot and overflow of settlers (C and CA) also pass to two classifiers (No. 2 group), the spigots ([illegible] in. diameter) of which join up and pass to an Isbell vanner, the overflow of the classifiers passing to settlers (G).

The tailings from the Wilfley and Buss tables are passed to two settlers (CB), the spigots of which join up and are sent to the molybdenite flotation plant (No. 1) sub-unit, the overflow being pumped back to the mill reservoir.

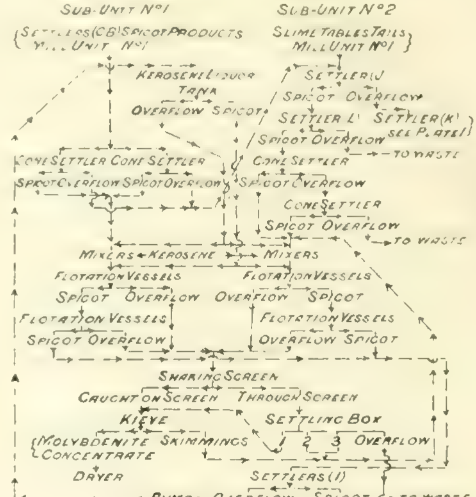
The tailings from the Krupp and vanner tables are passed to a settler (H), the spigot (¾ in. diameter) of which is passed to the molybdenite flotation plant (No. 2 sub-unit), the overflow going to the creek dam.

The spigot of settler (G) is run to slime frames, producing a low-grade concentrate and tailings, the overflow going to the waste settler (L). The tailings join up with the spigot of settler (H) and pass to the molybdenite flotation plant (No. 2 sub-unit). The spigot of settler (K) (see later), together with No. 2 head of the slime frame concentrates, is sent to a buddle (No. 1), the overflow going to waste. No. 1 head of this buddle, together with No. 1 head of the slime frame concentrates, is re-treated in No. 2 buddle. No. 2 head of No. 1 buddle is re-treated in No. 1 buddle, and No. 3 head is sent to waste. No. 1 head of No. 2 buddle is treated on a Luhrig vanner, producing bismuth-wolfram concentrates, middlings, and tailings. The concentrates are sent to the drying and magnetic separation room. The middlings are returned to the vanners, and the tailings sent to waste. No. 2 head of No. 2 buddle is re-treated in No. 1 buddle and No. 3 head sent to waste.

The bismuth-wolfram concentrates are dried, sampled, weighed, and assayed. They are then sized into three grades (through 30 mesh, through 16 mesh, and through 12 mesh) and magnetically separated. Any oversize is crushed and re-sized. Two magnetic separators of the Dalbouze bracket type are employed at work, the current used being 11 amperes at 110 volts. The product from the separators consists of clean wolfram concentrates and a bismuth concentrate containing the bismuth, together with a little wolfram. A small amount of iron residue is also obtained, which contains a small percentage of wolfram. These residues are dressed on a Wilfley table, producing a fairly high-grade wolfram concentrate, which is shipped with the concentrate above. The wolfram and bismuth concentrates from the separators are then ready for shipment.

The molybdenite flotation plant (see Fig. 2) consists of two sub-units, No. 1 dealing with the tailings from the Wilfley and Buss tables, and No. 2 dealing with the tailings from Krupp tables, Isbell vanners, and slime frames.

In No. 1 sub-unit the spigots from settlers (CV) are passed to two settlers of the cone type in order to be dewatered as much as possible. The dewatered pulp is passed to a mixer, the stirring blades revolving 175 r.p.m., the necessary oil required being added in this mixer. From the mixer the pulp is fed to distributors on No. 1 set of four flotation vessels. The flotation vessel is of the cone type, with an approximate diameter of 4 ft. 9 in. and depth 3 ft. 3 in. The distributor occupies 1 ft. 11 in. of the centre of the vessel, leaving 1 ft. 5 in. of the outer diameter of the vessel as flotation area. The spigots of No. 1 set of flotation vessel pass to distributors on No. 2 set, the concentrates passing to a dewaterer. The spigots of No. 2 set are sent to two large settlers (I), the liquor overflowing to the storage reservoir,



Molybdenite Flotation Plant.

and the tails passing to waste, the various overflows joining up at this point and providing the necessary flushing water. The concentrates from No. 2 set of flotation vessels join up with those produced from No. 1 set and pass to the dewaterer. The overflow from the two cone settlers is passed to a large settler (J), the spigot (½ in. diameter) of which is sent to No. 2 sub-unit, the overflow passing to a still larger settler (K). This precaution is taken in case of the overflowing of the two cone settlers, in addition to obtaining a better settlement of the fine material.

In No. 2 sub-unit, the tailings from the Krupp tables, Isbell vanners, slime frames, and spigot of settler (J) are sent to a large settler (L). The spigot (¾ in. diameter) is passed to two cone settlers, the overflow going to waste. The dewatered pulp from the cone settlers is then dealt with as in No. 1 sub-unit, the feed from the mixer passing to distributors on No. 1 set of three flotation vessels and concentrates to the dewaterer. The spigot of No. 1 set of flotation vessels passes distributors on No. 2 set, the concentrates joining up and passing to the dewatered. The spigots of No. 2 set of flotation vessels join up with the spigots of No. 2 set of No. 1 unit, and pass to the settlers (I).

The molybdenite concentrates also join up with that produced from No. 1 sub-unit, and together pass to the dewaterer. The molybdenite dewaterer is a rectangular box approximately 3 ft. long by 2 ft. wide and 6 in. deep. On the bottom of the box is placed 80 mesh screening. The liquor carrying the concentrates is led on to the box, the latter being given a shaking movement. The dewatered concentrate is periodically removed from the screen, the liquor and fine molybdenite passing through the screen into a large 3-compartment box. The fine molybdenite settles in this box, and the liquor overflows to the storage reservoir. The fine molybdenite in No. 1 compartment of this box is periodically removed and dressed in kieves to a marketable concentrate. The fine molybdenite in Nos. 2 and 3 compartments, together with the skimmings from the kieves, are periodically returned to the mixers. As much as possible of the liquor is saved and pumped from the storage reservoir to tanks above the mixers, thus providing liquor for the mixers and overflow of the flotation vessels. Loss in liquor is provided for by adding water when necessary to these tanks. The dewatered molybdenite concentrate is dried and is then ready for market. The concentrate obtained from the screen assays 85% to 94% MoS_2. The dressed concentrate from No. 1 compartment of the box assays 80% to 85% MoS_2, depending on the cleanliness of the water used in the flotation plant and the nature of the ore milled.

CORNISH GEOLOGY

At a meeting of the Royal Cornwall Polytechnic Society held on July 6, E. H. Davison read a paper entitled : "Some Recent Additions to our Knowedge of Cornish Geology." This consisted of a series of notes on new facts regarding the geology of Cornwall, both on the purely scientific side and as regards the economic side of the science, which have come to the author's knowledge during the last eighteen months. In most cases the original observations were made by one or another of his students at Camborne Mining School, sometimes as the result of suggestions made by others, at other times entirely original.

The occurrences described in the paper are as follows :—

(1) A new type of basic igneous rock from Porthglaze Cove, Gurnard's Head.

(2) A type of tourmalinized granite not previously described from Wheal Providence, Carbis Bay.

(3) An unusual form of altered elvan from Carn Menellis district.

(4) The occurrence of platinum in the alluvial gravels of the Lizard.

(5) The occurrence of gold in the Carn Menellis district.

(6) Green Clay on Goonhilly Downs.

(7) Fuller's Earth at Treamble.

(1) In August, 1920, Mr. Castier, who was then a student at the Mining School, and has since gone to the Ouro Preto mine, Brazil, noticed a strange rock at Porthglaze Cove, just to the northeast of Gurnard's Head. The author visited the cove and found in its western corner a basic igneous rock, with patches and lenticular areas of pale coloured more acid material, forming the cliff to a height of about 120 ft. above sea-level and for a distance of about 40 yards to the west. The rock has a black and pink foliated appearance, the black part being composed of hornblende, iron ore, and a little felspar, while the pink part is composed of altered orthoclase felspar with some sphene and apatite. The specific gravity is 2·82, and the general character of the rock reminds one of the Kennack gneiss of the Lizard, and it seems to have originated similarly from a magma composed of imperfectly mixed acid and basic material. The rocks in the immediate neighbourhood of this mixed rock are intruded by granite veins, the granite-slate contact being visible in the cliff 50 yards to the east. It has been suggested that the mixed rock originated as a result of the absorption of the "greenstone" by the granite, but the field relations of the two rocks do not support this view. The author is at present engaged in a thorough examination of the mixed rock, which should throw light on its origin. He has since seen a similar type of greenstone in the Botallack cliffs.

A microscopic study of the rock shows that the coarsely foliated character which is a common feature was the result of movement while the magma was still fluid and not of pressure subsequent to solidification.

(2) Early this year Mr. Simmonds brought the author a specimen of tourmalinized granite from Wheal Providence dumps, Carbis Bay, which has unusual characters. The rock occurred in the dump material, there being several blocks exposed when the dump was being shifted for road material. The rock shows pink orthoclase and quartz with coarsely crystallized prisms of tourmaline and nests of yellowish muscovite with some chlorite. At first sight it appears similar to tourmalinized granite of the luxulyanite type, but the tourmaline occurs in groups of well-developed prisms arranged parallel to one another and not in radiating needles of small size, as is the case in luxulyanite. The presence of the muscovite is another point of difference. The quartz and felspar frequently show pegmatitic intergrowth. The tourmaline also is seen to penetrate the felspar, and all four minerals (quartz, felspar, tourmaline, and mica) seem to have crystallized simultaneously to form a pegmatite.

(3) On a visit to Carn Menellis district last April the author came across a type of altered elvan which has unusual characters. The dyke of elvan (quartz-porphyry) is worked on the hillside just above Carn Menellis church, and is seen in the quarry to be a fine-grained rock of a pale buff colour composed of occasional phenocrysts of quartz and felspar in a fine grained felsitic groundmass. Scattered through the rock here and there are cubic crystals of pyrite which are oxidizing to limonite and are surrounded by a ring of red-brown iron stain. The altered type is of a pale yellowish-green colour which has been brecciated and recemented by quartz showing comb structure. Under the microscope the ground-mass is seen to be composed of an extremely fine-grained mosaic of quartz, chlorite, muscovite, and secondary silica. The original felspar phenocrysts have been entirely removed by silicification, and with the silica lithia micas have been introduced.

(4) When Dr. R. H. Rastall read his paper on "Ore Deposits of Igneous Origin" before the Cornish Institute of Engineers last April he suggested that according to the character of the Lizard rocks they would very probably contain platinum, and he considered that the best place to hunt for the metal would be in the alluvial gravels of the serpentine area. As the outcome of this suggestion two of the students (Messrs. MacPherson and Lamb) visited several localities on the Lizard and collected samples of the river gravels. The concentrate obtained by panning the samples from one locality was assayed and it proved to contain a very small quantity of platinum. They then obtained a prospecting licence and made a more thorough examination of the area, but unfortunately with no satisfactory results. It appears then that platinum undoubtedly occurs in the Lizard district associated with the ultrabasic rocks there, but not in quantities of economic importance. This is what one would expect considering the small amount of real alluvial material in the district.

(5) Another interesting occurrence (but not one which can be claimed as new) was confirmed by Messrs. Kitto and Linne, who, during the study of an alluvial area in the Carn Menellis district, found that the alluvial sands contained gold. This metal has been recorded from the district before, so that this cannot be considered a discovery, but it is interesting as confirming a previous report and as indicative of the wide-spread distribution of small quantities of gold in the county.

(6) Other economic products which are now being worked in the county and which can be considered as additions to the list of Cornish products, are :—

(*a*) The green clay worked in the Mullion district, which can be seen by the side of the high road on Goonhilly Downs to occur near the junction of the ancient Lizard granite and the serpentine.

(*b*) The St. Agnes Pliocene sand, which is now being dug for core sand.

(7) A clay deposit at Treamble, near Perranporth, was discovered by Stephen Clark, of Treamble, about 12 months ago. The clay occurs alongside the Great Perran iron lode in the clay slate on the eastern side of the Treamble valley, its analysis (communicated by Mr. Clark) being :—

	Fuller's Earth.	Clay Slate.
	%	%
SiO_2	56·37	55·00
Al_2O_3	24·20	23·08
FeO	0·42	8·16
CaO	0·31	5·36
MgO	0·29	2·52
Na_2O, K_2O	1·38	3·00
TiO_2	trace	
SO_3	trace	
H_2O free	12·4	
H_2O combined	4·58	
	99·94	97·12

The clay has been classified as a fuller's earth of exceptionally good quality. It seems to be connected with the branching of the iron lode at Treamble and with the intersection of the lode by a north and south fault. At the time of the author's visit, however, the deposit was not sufficiently well exposed to show its relations clearly. It is undoubtedly an alteration product of the clay slate, and the comparison of its analysis with that of the clay slate is of interest. This shows that in the change to the fuller's earth the slate has lost FeO, CaO, MgO, and some alkalies, silica, and alumina, giving a gross loss of solid constituents of 14·5%, which seems to indicate that leaching by water or solutions was the cause of the alteration.

THE GOUDREAU GOLD DISCOVERY, ONTARIO

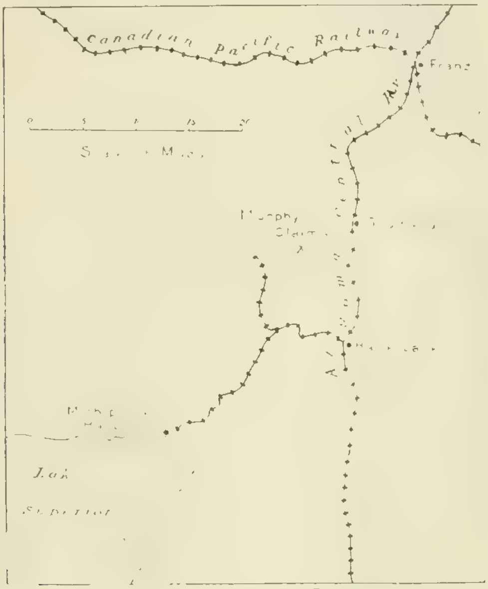
A discovery of gold was made by Thomas Murphy in April last at a point 3½ miles south-west of Goudreau station on the Algoma Central Railway, which is 17 miles south of Franz, a station at the crossing of the Algoma Central and the Canadian Pacific Railway. This region is in the Michipicoten area, bordering on Lake Superior, an area which has hitherto been known chiefly for its iron deposits, although the existence of gold was recorded in W. H. Collins' report for the Geological Survey of Canada issued in 1918. A. G. Burrows, of the Geological Survey, was sent promptly to examine the locale of the new discovery, and his preliminary report has just been received. At the time of his visit C. G. Daimpré was inspecting the Murphy claims, and on the latter's recommendation A. R. Porter, of Toronto, took an option on them. We quote from Mr. Burrows' report herewith.

The area is most conveniently reached from Franz, a station at the crossing of the Canadian Pacific and Algoma Central Railways. Goudreau, which is the nearest railway station to the gold discovery, is 17 miles southward from Franz ; the Murphy claims are about 3½ miles south-west from Goudreau. The camp is reached by a good canoe route, which starts ½ mile south of the station, and follows by way of Jackson, Long, Doherty, Aitken, and Murphy lakes. The longest portage is about 1 mile. The find is located near the north shore of Murphy lake.

The rocks in the area to the south-west of Goudreau are dominantly basic volcanics of Keewatin age. Rocks of this character were observed from Goudreau all along the portage route to Murphy Lake. The ellipsoidal structure, along with amygdules so characteristic of much of the Keewatin, is frequently seen. In places the basic lava contains considerable carbonate and is lighter-coloured than the normal dark-coloured rock. Most of the lavas are altered to schist, which has a general strike nearly east and west. With the lavas there is a small amount of banded iron formation, magnetite and silica. In the vicinity of Goudreau the main iron formation zone is prominent. Two of the large iron pyrites properties, the Goudreau mine of the Nichols Chemical Company and the Rand Consolidated Mines, are near Goudreau ; neither of these is in operation at the present time. With the basic volcanics in the vicinity of Murphy Lake there are several intrusions of quartz-porphyry of quartz-felspar-porphyry ; these acid rocks are generally schistose like the darker lavas. Some of the quartz-porphyry occurs as dykes cross-cutting the strike of the lava flows. A mass of grey granite, gneissic in places, occurs on several claims to the west of the gold discovery. Several narrow dykes of diabase with a north-west strike cut the older formation. One of these is an olivine diabase.

The first discovery of gold was made in a quartz

vein in the south-east part of claim 408, where, for a distance of about 20 ft. along the hanging-wall side of the vein, there are a number of showings of quite coarse gold in the quartz. The quartz vein has been traced by trenching and outcrops for about 800 ft. on claim 408. It strikes approximately N. 30° W., and the dip, where observable, is from 60° to 80° S. It varies in width from 7 in. to 3 ft. Along the quartz vein the wall-rock has been altered in places to a rusty schist containing ankerite and sericite and carrying quartz veinlets together with sulphides at different points. The width of the altered rock appears to vary greatly, but, owing to the small amount of cross-trenching, the width of the possible mineralized wall-rock could not be determined. The hanging-wall contact of the quartz and schist is more definite than the foot-wall. At the location of the gold showings, the vein, including the wall-rock, is about 3 ft. in width, while 15 ft. to the north is



Map showing position of Goudreau.

a subsidiary quartz vein a foot in width, to the north of which is a band of ankerite. Twenty feet to the west this smaller vein is only 3 ft. from the main vein. The quartz vein in places is well mineralized with sulphides, pyrites, copper pyrites, and pyrrhotite ; 150 ft. south-east from the above showing the quartz vein is about 7 in. in width and, in a thin band of sugary quartz and schist on the hanging wall, visible gold was seen.

Work has also been done on claim 407 to the east. At the west line, 200 ft. north of Murphy Lake, a narrow quartz vein about a foot in width has been traced 65 ft. ; it strikes S. 80° E. The wall-rock for a few inches is quite rusty and carries sulphides. Visible gold was observed at two points along the vein. About 200 ft. east from the west line work has been done on a wide ankerite-schist band up to 20 ft. in width, which carries quartz veins roughly parallel with the ankerite band. It has been traced for 170 ft. in a direction S. 70° E. No visible gold was observed in this vein, but at one point an assay of \$6·00 in gold was obtained over a width of 2 ft. 9 in. of quartz and \$4·00 in gold over a width of $5\frac{1}{2}$ ft. of the schist and carbonate, carrying quartz, lying to the north. Owing to the highly altered character of the schist by oxidation, the latter assay is only indicative of the presence of gold which may be concentrated. The quartz vein carries pyrite, copper pyrites, pyrrhotite, and a little zinc-blende. It is possible that this easterly vein is the faulted part of the vein exposed on claim 408. A number of assays of samples obtained at points along the veins showed gold values ranging from a few cents to \$28·00 per ton. In addition, two assays were made of specimens of quartz carrying a high percentage of sulphides from a pit a few feet west of the rich gold showings, which gave \$31·20 and \$48·80 in gold. The property, however, was not in condition for any thorough sampling since few cross trenches had been made exposing the walls of the vein and none below the superficial oxidation. The main vein shows high-grade ore for at least 40 ft. near the discovery, but extensive work will be required to determine the possible ore-shoots along the veins, since large portions of the vein are concealed by drift.

Mr. Burrows also gives an account of gold deposits north-east from Goudreau. Gold has been discovered on a number of claims between Goudreau station and Goden Lake.

The McCarthy-Webb group of claims near Iron Lake has been described by W. H. Collins in his report on the Magpie-Hawk area as already mentioned. Briefly, the rock is a schistose porphyry, which in places is a quartz-porphyry, with a strike N. 84° E. Shear zones occur in the porphyry, and these are indicated by a rusty surface containing vague quartz veinlets, which is in marked contrast to the white porphyry. The rusty streaks are very irregular in length and breadth, being from a few inches to a few feet in width, containing fine-grained iron pyrites. Gold in a very fine state has been found in the rusty zones. In addition, there are widely separated transverse veinlets of quartz carrying much tourmaline, in which coarse gold has been discovered. These veins are more definite than those running with the schist. The property has been sampled several times, particularly in one place for a length of 100 feet, where the rusty condition is most pronounced.

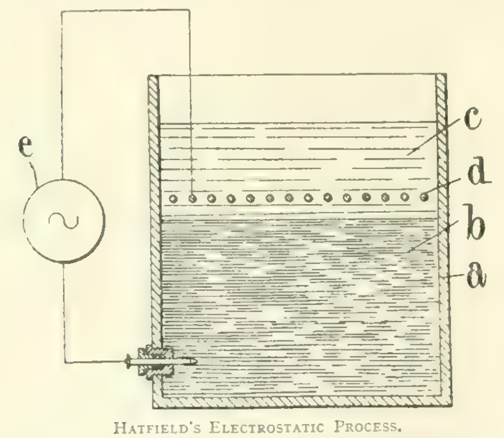
The Morrison claim on the north shore of Goudreau Lake is similar to the McCarthy in structure. However, the rusty zones running with the schist are less pronounced, while there are more of the transverse quartz-tourmaline veins. Visible gold has been found in a number of the narrow veins which are parallel to the schist and also in the transverse veins.

The Cline claims about $1\frac{1}{2}$ miles north-east of Pine Lake were also visited. Visible gold was seen on two of the claims. The rocks are Keewatin schist in which narrow quartz veins have been formed. A shaft was sunk 25 ft. in a quartz vein from $1\frac{1}{2}$ in. to 6 in. in width, in which there is a high percentage of sulphides and visible gold. The extension of the vein to the west, where it was cut by a diabase dyke, has not been found. On another claim there is one narrow rich quartz vein about 5 in. wide in which gold has been found over a length of 20 ft. A second vein from 8 in. to 3 ft. wide occurs on the claim. It consists of quartz and schist on which a 5 ft. pit has been sunk. Material from this vein showed much gold on panning. Owing to the heavy drift covering it

[illegible] the vein [illegible] distance. Some [illegible] were also observed on another [illegible] trench the rusty zone is 15 ft. in width, which [illegible] rapidly to the west. Some visible gold is reported near the north wall. [illegible] work has not been done on any of these claims to determine their value.

Tin Concentration.—British Patents 3,809 and 31,212 of 1920, combined as No. 165,892, describe the invention of H. S. Hatfield for electrostatically separating materials when suspended in liquid mediums. This process has been mentioned in the reports of the Department for Scientific and Industrial Research as applied to the treatment of slime tin, but details of its nature have not hitherto been published. The specification is a long one, and we merely give brief extracts.

According to this invention the powder whose constituents are to be separated one from another is suspended in a liquid the dielectric capacity of which lies between that of the constituents of the said powder. Electrodes in the liquid are connected to an electric supply of considerable potential, preferably alternating; an electrostatic field between the electrodes is thereby produced. Those suspended particles of greater dielectric



HATFIELD'S ELECTROSTATIC PROCESS.

constant than the liquid will then be found to move so as to place themselves along the shortest lines between the electrodes; that is, in the strongest part of the electrostatic field. On the other hand, those particles of less dielectric capacity than the liquid will move out of the electrostatic field between the electrodes. As an example of the separations to which this invention may be applied, the cassiterite in tin ore when suspended in aniline is strongly attracted, while the gangue is not affected. The conductors used may be 0·25 to 1 millimetre apart, and be charged with alternating current of 200 volts. For the separation of cassiterite, and for separation generally, a mixture of nitrobenzene and paraffin oil, which may be adjusted to any desired dielectric constant between 2 and 36, is very useful. With fine suspensions it is necessary sometimes to add an agent which produces deflocculation of the suspension. In carrying the invention into effect in one form as shown in the figure, a vessel *a* is provided containing in its lower part a quantity of water, acid, alkali, or salt solution, or other electrically conducting liquid *b*. Upon this liquid floats another liquid *c* which is that used as the medium of suspension and chosen so as to have a dielectric constant intermediate between those of the particles which are to be separated from one another. In this liquid *c*, and as close as practicable to the boundary of the two liquids, is a perforated electrode *d* connected to one of the poles of an alternating electric supply *e* the other pole of which is led to the electrically conducting fluid in the bottom of the vessel *a*. The solid to be separated is then fed either dry or mixed with a little of the suspension medium into the top of the vessel. It then passes through the perforated electrode *d* and that part of it having a dielectric constant greater than that of the suspension medium comes to rest upon the boundary between the two liquids, while that part of it having a dielectric constant less than that of the suspension medium is immediately forced through the boundary between the two liquids into the lower liquid *b*. Pure capillary forces act upon the solid at the boundary between the two liquids, which either oppose or assist it to pass into the lower liquid *b*, and the success of this method in any given case will therefore depend to some extent upon these forces, and can only be determined by trial. It is found that if amyl alcohol be used for the liquid *c*, and water for the liquid *b*, cassiterite may be separated from gangue, the gangue passing into the water and the cassiterite remaining behind.

Geological Investigations in Rhodesia.—In the Report of the Rhodesian Geological Survey for 1921, H. B. Maufe, the director, gives an account of investigations in the Lomagundi district. He made three traverses into the outlying districts, one of which included a visit to the recently opened mica field. The number of mica deposits and quality of the mica (muscovite) are favourable to the establishment of a mica-mining industry. On this and on another traverse westwards into the Sebungwe district the beds of the Lomagundi system were shown to have a far wider extension than was previously known, and some observations were made on the varying degree of metamorphism of the beds. In this connexion it was pointed out that if the graphitic slates of the Lomagundi system were found to extend into the areas of higher crystallization, it was probable that workable deposits of flake graphite might be found. Since then some very promising flake graphite has been discovered. Among the minerals identified on the mica field is beryl, often in greenish and bluish green tints, which render it probable that aquamarine of gem quality may be found. Other minerals discovered in place on the mica field comprise a few known previously in the Somabula diamondiferous gravels and include the indicator staurolite. The source of these minerals had been a puzzle hitherto.

A third traverse included an examination of the chrome deposits in the Umvukwe hills. The chrome iron ore occurs in seams generally less than one foot thick in the central portion of the Great Dyke. The occurrence of the chrome ore has been aptly compared by A. H. Ackerman to that of a series of coal seams lying one above the other in a basin. The seams dip towards the median line of the dyke at moderate angles, which diminish towards the centre, and there is good reason for believing that the seams extend across from the outcrop on one side to that on the other. The country rock of the seams is usually an enstatite rock partially or wholly altered to serpentine, but on some claims a chromite

seam has a floor of enstatite rock and a roof of serpentine, which appears to be derived either from a dunite or a saxonite. The synclinal structure of the dyke is similar to that already described in other portions, notably by Dr. Wagner in the Belingwe district. The origin of the structure, formerly a purely scientific question, has now become of importance to the chrome miner, and will require elucidation. The occurrence of the chrome iron ore in the Great Dyke is thus quite different from that of the chrome in the well-known deposits at Selukwe. The chrome iron ore in the Great Dyke can, it appears, be picked clean to assay over 50% chromic oxide, and the resources of the Great Dyke in this mineral must amount to many millions of tons.

The chrysotile asbestos now being worked in the Great Dyke is situated near the western edge of the dyke, where the northern continuation of the dyke offsets to the east nearly a mile. The offset appears to be due not to a fault, but to the presence of a large quartz reef in the granite country rock. That the line is one of weakness is shown by the presence of a later dolerite penetrating the Great Dyke close to the line of the offset. The asbestos seams are vertical, of a high average width, and trend in a general east and west direction, being spaced irregularly through the country rock as in the older asbestos deposits. The country rock is serpentine derived so far as could be ascertained by eye partly from an enstatite rock and partly from a saxonite. It is not yet generally realized that the chrome and asbestos deposits occurring in the Great Dyke are very much younger in geological age than the Selukwe chrome, and the Mashaba and Shabani asbestos deposits.

Distribution of Gold in Banket. — At the June meeting of the Chemical, Metallurgical, and Mining Society of South Africa, the new President, F. Wartenweiler, presented a paper on the distribution of gold in banket ore. The constituents of the banket and of the associated quartzite, shale, and dyke rocks, which constitute the ore treated, have been described by a number of investigators; the most familiar description is perhaps that by R. Young, in the book entitled *The Banket*. Both A. F. Crosse and W. A. Caldecott dealt with the constituents of the milled ore many years ago (see *Journal of Chem. Met. and Mng. Soc. of S.A.*, vol. iv, 1903–04, pp. 104 and 110; and *Transactions of Inst. of Mining and Metallurgy*, vol. xiv, 1904–05, The Finer Crushing of Banket Ore, by W. A. Caldecott). Lack of detailed information and the necessity for knowledge on the subject being brought abreast of current practice led to an investigation, the main features of which are given herewith. It was begun several years ago at the Rand Mines laboratory, with the primary object of ascertaining the gold distribution in the ore constituents of the products into which the comminuted ore is classified after amalgamation. Since then the information gained by the method, when applied on samples from different mines, has been found to be of considerable use in controlling reduction works operations. For the purpose in view, it was thought that if a clean separation were made between the pyritic and the gangue portions and their relative gold value determined, the information sought would be acquired. After preliminaries with Sonstadt solution and with flotation, the latter method was decided on as preferable. Tests were begun, using a motor-operated laboratory flotation machine, supplemented by panning of the tailing to separate any coarse pyrite and gold which had not been lifted with the froth. All samples for flotation were ground to pass a 150 mesh linear screen. Various flotation oils were given a trial, the combination finally adopted as the most effective being wood tar oil and turpentine, in a circuit acidified with sulphuric acid. It was found necessary to vary the amount of acid with the class of product treated. A final washing effect in respect to pyrite was secured by the addition of a fractional quantity of wood tar oil toward the end of the flotation agitation. The separation of the pyritic portion was, by observation, clean, this being confirmed by sulphur determination in the tailing, which gave such low sulphur content in terms of pyrite as 0·16% FeS_2 and 0·08% FeS_2. As free gold, not encased, will float in the frothing process, the pyrite, unless otherwise noted, also includes this floated gold. Its incidence was ascertained in several tests. No distinction was made between the argillaceous and the siliceous portion of the gangue. It is known that the truly argillaceous portion is small at the mines of the central district, but is increased at the extreme eastern mines by the inclusion of much shale.

The first data (series *A* and *B*) were derived from tests on samples from the Ferreira Deep reduction plant. These tests were carried out in two series, one in which the agitation and frothing was continued to an extreme extent with the object of ensuring a clean pyrite-free tailing, and the other in which flotation was carried on only to the limit of the clean mineral froth stage, the object being to obtain a clean gangue-free pyrite. The results are given in tabular form by the author, and from them it is seen that the argillaceous and siliceous portion of the slime residue contains the greater part of the gold (60·1%), while the gold in the cyanide pulp is found to the extent of 87·5% in the pyrite portion. In Series *B* the percentage of pyrite by weight, separated by the flotation method, plus panning, corresponds closely with the FeS_2 calculated from sulphur determinations. From a study of this record it is evident that the gold in the pyrite portion of the slime charge dissolves readily in cyanide solution.

Further tests (Series *C*) were conducted on a sample of cyanide pulp, and on a sample of sand charge, and the corresponding residue from the Village Deep plant. The results showed that the gold in the cyanide pulp is distributed 37·5%, 51·4%, and 11·1% respectively, as free gold, in pyrite, and in gangue. When investigating the sand charge and residue, gold encased in the siliceous matrix was determined by the aqua regia method. It does not appear to play much of a part in the residue. If the seal of accuracy be attached to this method of determination, one would accept as established that the cyanide solution penetrates the ore particles and dissolves encased gold. The amount of gold amalgamable in cyanide pulp and in the sand charge, 37·5% and 19·4% respectively, varies with the grinding. It is a revelation, and confirms the general tendency in practice to throw more responsibility for gold recovery on the cyanide section of the plant and less on amalgamation. In considering the distribution of free gold, pyrite, and gangue, it is observed that the first two comprise 90·3% of all the gold in the charge.

A comprehensive series of tests [illegible] were carried out on a City Deep sand charge and the corresponding residue. Free gold was not determined in this series, and is, therefore, included in the pyrite value. Under pyrite content the percentage of gold content is found to increase considerably in the gangue portion of the residue, evidently due to encased gold. Grading analysis discloses the increase in gold percentage content in the coarser gradings, comparing the charge with the residue. The large amount of pyrite by weight and the importance of gold content in the minus 200 mesh grading of the charge is significant, especially when viewed in the light of improvement to extraction on this fine pyrite. All the information in the author's tables under "distribution of gold extraction" and "extraction on pyritic portion" points to the great importance of grinding the maximum amount of pyrite and gold as fine as possible to pass the 200 mesh at least, in order to obtain the highest extraction. Although this has been accepted as an axiom by many workers in this field, it is the aim of this paper to so illustrate and visualize it that it will become forcible to all those interested. From a practical metallurgical standpoint this investigation points to this one significant fact of the need for comminution of the pyrite.

The importance of careful classification and tube-milling follows. If the classifiers do not return the plus 200 mesh pyrite and free gold to the tube-mills for further grinding, then the plant is indeed handicapped. On the ores of the extreme eastern district the application of this maxim is of the greatest importance.

Mining Efficiency.—The question of improving the standard of efficiency and introducing methods for securing economy of working is prominently before the whole mining community in the Transvaal at present, the universal feeling being that something must be done to prevent the untimely closing of most of the low-grade mines. The general question is in the main political, and secondarily it centres round the rule of the men's unions. But apart from these considerations there are many points of detail that can be discussed by the managers and taken into account by both white and black labour. The *South African Mining and Engineering Journal* recently offered a prize for the best essay on "How to Reduce Working Costs and Improve Efficiency in and on the Mines of the Witwatersrand." The prize has been awarded to John Moore, of the Crown Mines. The essay is brief but full of good sense, and we reproduce it here. We would mention also that a paper has been read before the South African Institution of Engineers by F. C. W. Ingle covering the same subject. Copies have not yet arrived in this country, so publication of extracts must be postponed until a later issue.

We quote Mr. Moore in full as follows :—

There is no one thing that will cut the cost of production sufficiently for the low-grade mines to resume work at once. However, a lot of small reductions will cut the costs of the mines at present working and the mines now closed down will be able to resume work, slowly at first, and later on to open up on their former scale.

Firstly, considering surface conditions :—

(1) There is an immense amount of scrap iron and steel that could be remelted to produce pig iron, either for mine consumption or for sale. One blast-furnace for the group would probably be sufficient. That it is possible for a group to make all their own castings, including special alloys for stamp shoes, etc., has been proved by the Calumet and Hecla.

(2) Overlapping authority and petty foremen must be got rid of.

(3) There are mines to-day with a comparatively small tonnage with surface costs of 4s. per ton. Others with large tonnage and surface costs of 7s. per ton. This disparity of costs is startling.

Secondly, underground :—

(1) The repair of worn tools should be undertaken to a greater extent than is at present practised. Shovels, for instance, could have the blades patched when worn, and broken handles replaced by ¾ in. or 1 in. pipe. One end of the pipe can be split and a rivet put in to form the usual D grip. For actual shovelling these are not as good as a new shovel, but for the scraping that is usually done they are just as good. Pipes to be cut and threaded and old taps and valves to be brought to surface, cleaned up, and repaired. New issue should be given only in special cases unless old gear is turned in with the order for new.

(2) Axes and saws, etc., should be exchanged for sharp ones as soon as dulled. This should be done at an underground store, as the delay is often several days before tools left on a station are brought to surface. In the meantime they are rusting and there is a chance of them getting lost. One saw at the present price would pay for a boy two hours per day for a month, to say nothing of the inconvenience caused.

(3) Timber is one of the heaviest costs, especially on the Central Rand. This may be cut down, especially in low slopes, in hammer and reclamation work, by the use of old heavy-section rails in place of sticks as foundations for waste packs. They must be well hitched into the foot and have head boards. A platelayer can cut them to the timberman's measurements in a very few minutes.

(4) Instead of the universal lagging, old pipes may be used across the rails in place of a backwall.

(5) When travelling ways must be kept open, especially when the ground is very heavy and the height not more than 6 ft., waste packs may be built as follows : A layer of stones carefully packed about one foot thick, then across this old hauling rope unravelled and the strands cut to such a length that they reach twice across the pack with the ends away from the travelling way. These are placed about one foot apart. Another layer of stone, and this time the strands are laid at right angles to the first. These so bind the pack that it will crush to about two-thirds of its original height without bulging. The ordinary pack will crush very little before bulging.

(6) There are many other ways of saving timber, reclaiming some distance from the faces, etc., that are used everywhere, but the two above are not in common use on the Rand.

(7) At present the native labourer spends on an average of two hours per day in a prescribed waiting place till his boss takes him to his working place. In bad ground it is admitted that a white man should always be present, but in the average stope a timberman or trammer could inspect the working place, start the boys, and then go to the more dangerous places where constant supervision was necessary. These men would go down, say, two hours before the ordinary shift. This would allow about two hours extra working time for the

natives at no additional cost to the mine. It would also solve the native labour shortage. In the case of hammer and machine boys, they would not be allowed to drill, but could lash benches, set up, and generally get ready for the day's work. [These conditions have since been improved.—EDITOR.]

(8) The items discussed above all influence the cost of production, but the most important of all is to give the day's pay man an added incentive to put his head and back into the work. This alone will restart every low-grade mine on the Rand. A man working for himself will do twice as much as a man on day's pay, and do it easier. To cut the day's pay man's wage, no matter what the excuse, most certainly will not do it, and, on the other hand, a glance over the cost sheets of American and Canadian mines will show that, conditions being equal, the mines that pay the best wages have the lowest labour costs per ton.

The following bonus scheme is working successfully in a number of places. The usual guarantee or day's pay is given, and a bonus is given for points above a certain set standard, and debits for below that standard. The standard would be set for each mine captain's section, or, if possible to keep the tonnage separate, for each shift-boss's section, and would be based upon tonnage (skip or haulage), grade (sample office), native and white efficiency. The tonnage and native and white efficiencies could be taken as an average per day for, say, the three months previous to the adoption of the scheme. The unit of tonnage might be taken as 1,000 tons, the efficiency unit as one ton, and the grade unit as one dwt. This would require some slight modification in exceptional cases, such as in a section which was just being opened up or where several stopes were stopped simultaneously. This only applies to the day's pay man; the contractor would not benefit by it in any way. The day's pay man would get his bonus cheque some time after the first of the month. By making every man virtually a contractor his best work would be secured and no man would see another loaf if his own bonus cheque was imperilled, no matter what the union said about it.

(9) Another change that would make a difference on the right side is to give the shift-boss his old control over his men. The Chamber of Mines did a bad thing when they took the power out of the shift-boss's hands. Admittedly it was abused at times, but if members of the Chamber had to go underground as shift-bosses to-day and keep up the standard they expect shift-bosses to keep up, there would be a change before night to the old way. Increase or decrease of working costs and native and white efficiencies are the true indications of success or otherwise, and a glance, especially at the latter, will show it has not been a success.

Operation of Mine Fans in Combination.—At a meeting of the Mining Institute of Scotland held last month, a paper by David Penman was presented, dealing with a new method of measuring ventilation resistances, with special reference to the operation of mine fans in combination. His general conclusions with regard to fans in combination were as follows: (1) The advantage to be gained by two or more fans in series or in parallel depends chiefly on the relation existing between the resistance of the fans and that of the mine. (2) Unless the resistance of the fan is small compared with that of the mine, the operation of two fans in series will result in a greatly lowered efficiency. (3) Unless the resistance of the fan is at least one-third of the resistance of the mine, the advantage of running two fans in parallel is small. (4) If the resistance of the fan is small compared with that of the mine, not only will the increase of quantity by parallel operation be small, but a slight reduction or increase in the speed of one of the fans over the other will result in the air being reversed in that fan which runs at the slower speed. (5) If increase of quantity is the sole desideratum, better results will in most cases be obtained by combining the fans in series than by running them in parallel. (6) The increase of quantity obtained by running two similar fans in series at the same speed at which they would run singly would in most cases be approximately 35%. (7) The increase of quantity obtained by running two similar fans in parallel would range from 5 to 15% in the majority of mines in Great Britain. (8) The satisfactory running of two fans in parallel can best be accomplished through the medium of synchronous electric motors. (9) If two fans are running in parallel and the speed of one should fall to any extent, the other fan may become dangerously overloaded, unless there is a large margin of power available in the motor or engine driving it.

Moisture in Furnace Blasts. — In the *Engineering and Mining Journal* for August 13, J. H. Gillis gives a record of observations with regard to the effect of moisture in the air delivered as blast in a copper-nickel blast-furnace.

In March, 1920, an exhaust pipe was so placed that the small amount of steam escaping was being drawn into the intake of a certain blast-furnace blower. Some days elapsed before this was corrected, and the incident was soon all but forgotten. Some weeks later, when the author was making investigation as to certain operating conditions, it was noticed that there was a particularly favourable period extending over a few days, with no corresponding favourable conditions to account entirely for it. After eliminating other factors to determine the cause of these conditions, he came to the conclusion that, as it corresponded with the period in which the steam was being drawn into the intake, possibly the extra moisture was the factor sought. The data, however, were not conclusive; they were affected by other conditions and could not be taken as definitely establishing much basis for future investigation. A search of the available literature on the subject, and discussions with the local metallurgists, failed to explain the results observed, and it was October before further experiments could be made. A test was then determined upon, and a ⅜ in. pipe was connected between the air main and a steam pipe carrying 180 lb. of steam with 100° F. of superheat. A decided change in the operation of the furnace resulted, but here, again, the results were confused by other factors. The experiments were continued, and larger quantities of steam were added, but the results after the first few days were negative. The steam would be turned on and gradually increased, with the result that at fir[illegible]
the furnace would speed up, and crusts
accretions would be eliminated, and then [illegible] 260
effects would disappear. No bad e[illegible] 260
observed, however, until sufficient st[illegible] ....
so that the water from the cond[illegible]e 261
blast began to give trouble aro[illegible]

were available, but deductions [illegible] crusl[illegible]solidated Main
[illegible]

the temperature of the blast and its moisture capacity. The experiments were eventually discontinued owing to inability to get definite results.

After study of the various operating curves covering the period of the experiments, the author came to the conclusion that he had been using too much steam, and decided to make another trial as soon as a favourable opportunity presented itself. About the end of January, 1921, after two weeks of uniform furnace operation, the steam was again connected, and a very small amount used. The temperature of the air outside ranged between zero and freezing, and the air in the blast main about 70° F. above that. Sufficient steam was added so that the air was just saturated; that is, some condensation showed in the valves and beds of the pipe. Rough calculations indicated that about 300 lb. of steam was used per hour, or 7,200 lb. per day, which at the cost of evaporation (which was high that month), amounted to $7·20 per day for steam. The tabulated results show an increased tonnage of 14·7% for the two days of the test over the average of the five days' previous, and at no time, even with the use of extra coke, had it been possible to make the same record without steam, although in the previous experiments it had been nearly equalled on several occasions. There was no change in any other operating condition during the period and no material change in the weather. The first day's run does not coincide exactly with the period for which steam was on, as the statistical day started at 7.30 a.m. and steam was connected about 9.30 a.m. On the third day the furnace was down a few hours to change the spout, and the author had no opportunity of making further tests. Although the results given show increased capacity only, there are reasons to believe that corresponding savings in operation costs could be made through saving in coke and flux and in smooth operation.

FURNACE PERFORMANCE BEFORE AND DURING THE TEST

	Ore	Flux	Coke	Per cent of Coke on Ore	Per cent of Coke on Charge
Five days previous to test	811·20	[illegible]	119·00	14·7	10·4
	811·20	[illegible]	116·00	14·4	10·2
	[illegible]	[illegible]	107·30	14·0	10·0
	712·85	269·00	99·85	14·0	10·0
	713·60	306·70	116·70	14·3	10·4
First day of test ..	896·40	315·40	125·44	14·0	10·4
Second day of test	899·10	316·35	127·45	14·2	10·5

The furnace was 50 in. by 30 ft., of ordinary water-jacketed type, and was smelting raw pyrrhotite ore with converter slag as flux. The results obtained indicate an advantage to be gained by the use of steam in smelting sulphide ores, and tests could be conducted at little expense in almost any plant, which would tend to increase the available information on the subject and perhaps make a material saving on operating costs. The author is desirous that other metallurgists should contribute to this discussion.

SHORT NOTICES

WOL- **centration Problems.**—At the meeting of to resul- and Institute of Mining, Civil, and up on the Engineers held at Sheffield on Firstly, co- nley Nettleton read a paper entitled (1) There is ent of Minerals, indicating a new and steel that ating minerals. We intend to iron, either for m vith some comment, in the next blast-furnace for

Coal Mining by Steam Shovel.—At the meeting of the Institution of Mining Engineers held on September 14, George Sheppard read a paper on coal mining by steam shovel in Alberta.

Grinding Problems.—In *Chemical and Metallurgical Engineering* for August 10, H. W. Hardinge reviews the modern problems of grinding, wet and dry, to various stages of comminution.

Flotation.—The *Mining and Scientific Press* for July 30 gives particulars of the Lockenbach flotation process, in which a frothing and selecting agent consisting of pine-pitch in an alkaline solution is employed.

Nodulizing.—In the *Engineering and Mining Journal* for August 13, C. L. Colbert describes the latest nodulizing practice for flue dust and fine concentrates at the United States Metal Refining Co.'s works at Chrome, New Jersey.

Chloride Volatilization.—The *Mining and Scientific Press* for July 30 publishes an account by T. Varley and C. C. Stevenson of investigations into the chloride volatilization process. Articles on this subject by Ben Howe and S. Croasdale were published in the MAGAZINE for December, 1913, and March, 1914, respectively.

Geological Sections.—At the meeting of the Institution of Mining Engineers held on September 14, Harry Roscoe read a paper entitled: Suggestions for the Standardization of Geological Sections of Strata proved by Bore-holes, Shafts, etc.

Spitsbergen.—The *Geographical Journal* for July contains an illustrated paper by J. M. Wordie on present-day conditions in Spitsbergen. The author is one of the geologists connected with the exploration of Spitsbergen.

Engels Copper Mine.—In the *Mining and Scientific Press* for July 30, A. B. Parsons commences an article on the Engels copper mine, California.

Graphite.—In the *Engineering and Mining Journal* for August 6, B. L. Miller reviews the graphite industry of the United States and Canada, giving an account of modern methods of concentration.

Copper Deposits in Arizona.—In the *Engineering and Mining Journal* for August 13, G. J. Mitchell describes replacement copper deposits in the Warren district, Bisbee, Arizona.

Pulverized Coal.—The *Engineer* for August 19 contains a description of the Bettington boiler, using pulverized coal as fuel, made by the Fraser and Chalmers Engineering Works, Erith.

Oil and Pulverized Coal.—In *Chemical and Metallurgical Engineering* for August 3, G. S. Perrott and S. P. Kinney describe the Trent process, according to which powdered coal in water is treated with comparatively large volumes of oil, the pure coal and the oil forming a plastic fuel, while the ash remains in the water.

RECENT PATENTS PUBLISHED

☞ *A copy of the specification of any of the patents mentioned in this column can be obtained by sending 1s. to the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. 2, with a note of the number and year of the patent.*

5,224 of 1920 (139,216). J. E. KENNEDY, New York. Improvements in gyratory crushers.

7,848 of 1919 (165,822). W. M. MORDEY, London. Electro-magnetic separators for the treatment of minerals, consisting of inclined launders with an alternate current multiphase magnet underneath which diverts the magnetic material to one side of the launders.

11,185 of 1919 (126,626). P. DESACHY, Paris.

Improved apparatus for making lithopone, that is, a mixture of barium sulphate and zinc sulphide.

17,745 of 1919 (165,465). F. CALVERT, Manchester. Improved practice in adding fluor-spar in steel purification.

1,375 of 1920 (166,292). ROPEWAYS, LTD., and E. ROE, London. Improved raising and lowering tackle for aerial ropeways.

5,561 and 35,632 of 1920 (166,929). J. J. COLLINS, Southport. In the treatment of zinc-lead and like sulphide ores and concentrates for the separation of the zinc from the lead, subjecting the crushed ore or concentrate while in a solution of a lower chloride of a metal to the action of gaseous chlorine, whereby the lead is converted from the sulphide to the chloride which precipitates on cooling, while the zinc sulphide remains substantially unattacked, drawing off the solution of the lower chloride of a metal from the zinc sulphide, lead chloride, and sulphur, and dissolving the lead chloride in a hot saturated solution of sodium chloride, leaving the zinc sulphide and sulphur.

9,149 of 1920 (141,044). AMALGAMATED ZINC (DE BAVAY'S), LTD., Melbourne. Improvements in patent 135,968, dealing with the separation of mixed chlorides by brine solution for the recovery of lead and silver from complex ores.

9,445 of 1920 (141,688). ELECTROLYTIC ZINC CO. OF AUSTRALASIA, LTD., Melbourne. Method of recovering cadmium in the course of the electrolytic process for producing zinc.

9,846 of 1920 (166,647). A. M. MACKILLIGIN, London. A machine consisting of a number of jumpers for drilling holes in a row and operated in much the same manner as stamps.

10,959 of 1920 (166,695). J. J. COLLINS, Southport. A process of purifying tin, consisting in producing pure stannous chloride from the impure metal by the action of stannic chloride on the latter in the presence of an excess of tin, dehydrating, fusing, and electrolysing the stannous chloride, whereby pure metallic tin and stannic chloride are formed.

11,116 of 1920 (142,122). H. MEHNER, Charlottenburg. A process for the manufacture of cyanogen by reaction between carbon, nitrogen, and the vapour of an alkali metal, in which the free alkali metal is introduced in the reaction space, together with a combined alkali metal of such nature that no reaction between the free and the combined alkali metal can occur during the process.

13,775 of 1920 (166,409). C. LANGER, Woolhampton. Method of separating metals such as copper and nickel electrolytically and depositing them simultaneously by employing two electric currents of different potentials.

14,625 of 1920 (143,920). ELEKTRO-OSMOSE GRAF SCHWERIN GESELLSCHAFT, Berlin. A process for concentrating by the flotation method finely comminuted ores containing electro-positive and electro-negative particles, wherein there is caused to act on the finely comminuted ore in aqueous suspension, for the purpose of separating one set of particles from the mixture, an electrolyte having an electric charge of the same character as that of the set of particles to be separated, and wherein for the simultaneous or subsequent flotation concentration there is used as floating agent a substance which does not prevent or destroy the sol-condition.

15,901 of 1920 (167,048). H. WALKER, Christchurch, New Zealand. In order to provide oxygen and moisture at the same time as firing shots in mines, using a cartridge containing permanganate of potash, chlorate of potash, and gum arabic, in association with the blasting cartridge.

16,701 of 1920 (165,655). SKINNINGROVE IRON CO., LTD., and T. R. SMITH, Saltburn, Yorkshire. A negative electrode for use in an electrostatic dust-depositing plant, consisting of chain-mail or the like supported at the top on a stationary bar and with a heavy bar attached to the bottom edge thereof, in combination with mechanism for lifting the heavy bar at intervals and allowing it to fall in order to impart a jerking action to the electrode.

17,062 of 1920 (146,133). SOCIÉTÉ ELECTRO-METALLURGIQUE FRANÇAISE, Paris. Method of preparing aluminate of lime for the manufacture of pure alumina, which consists in dividing the operation into two phases and making use of two apparatus ; in the first phase crushed bauxite mixed with lime is heated in a rotary furnace constituting the first apparatus, which is heated by waste heat from the second apparatus, and in the second phase the mixture is discharged from the rotary furnace into the second apparatus which is a furnace heated and arranged for effecting the fusion of the mixture, which on being discharged may be cooled and granulated in water.

19,014 of 1920 (161,104). F. MILLIKEN, Lawrence, New York. An alloy capable of resisting high temperatures consisting of chromium, copper, nickel, manganese, and 16 to 20% iron.

20,253 of 1920 (153,560). S. STEINMETZ, Berlin. Improvement in disc crushers.

23,238 of 1920 (161,491). DWIGHT & LLOYD METALLURGICAL COMPANY, New York. Improvement in the inventors' apparatus for continuous ore-sintering.

32,585 of 1920 (161,130). SVENSKA DIAMANTBERG-BORRNUNGS AKTIEBOLAGET, Stockholm. In ascertaining the inclination of bore-holes, the employment of a solution from which a etallic deposit can be precipitated electrolytically by making connexion when desired, instead of the etching solution hitherto employed.

32,715 of 1920 (165,708). T. G. NYBORG, Hexham, and M. F. HIGGINS, Sheffield. Method of fixing the tube bringing clearing fluid to the points of percussive drills.

35,794 of 1920 (166,490). S. DAWSON WARE, London. A jig having one or more power-moved screens or screen-trays covering practically the whole area of the tank or hutch, suspended from an overhead framework, vibrated or reciprocated both vertically and horizontally by two independent positive quick-return motions.

36,492 of 1920 (164,681). E. CUDNEY, Stege, California. Improved electric blasting fuse.

801 of 1921 (156,739). F. KRUPP, Magdeburg-Buckau. Improved form of plates used in filter-presses.

4,518 of 1921 (165,719). G. H. T. RAYNER and P. RAYNER, Sheffield. Valve apparatus for rock-drills and similar tools, comprising a three-collar valve, said collars being of equal diameters, characterized in that the central collar controls th main fluid supply and diverts it alterr 260
each side of the piston, the piston op
closing valve-throwing ports from the c 260

NEW BOOKS, PAMPHLETS, Etc.

Copies of the books, etc., mentioned below can be obtained through the Technical Bookshop of *The Mining Magazine*, 724 Salisbury House, London Wall, E.C. 2.

Quin's Metal Trades Directory of the United Kingdom, 1921. Cloth, octavo, 300 pages. Price 10s. 6d. net. London: The Metal Information Bureau, Ltd., 7, East India Avenue, E.C. 3. This is the first issue of a book which gives classified information relating to the non-ferrous metals business of this country.

South African Engineers Electrical and Allied Trades Directory, 1921–1922. Cloth, octavo, 490 pages. Price 30s. net. Johannesburg: The *South African Mining and Engineering Journal*, London Office: 82–5, Fleet Street, E.C. 4.

First Aid and Rescue Work in Mining. By Dr. L. G. Irvine. Flexible covers, pocket size, 370 pages, illustrated. Price 8s. 6d. net. Johannesburg: The South African Red Cross Society. London: The Mining Magazine.

Talc; Fluor-Spar.—Published by the Imperial Mineral Resources Bureau. Price 9d. each.

Income Tax Guide, 1921.—By H. W. Palmer. Price 1s. net. London: *The Financial Times*.

Mineral Industry of the British Empire and Foreign Countries.—Statistical Summary of Production, Exports, and Imports, 1913 to 1920. Published by the Imperial Mineral Resources Bureau. Price 3s. net.

Concentration by Flotation.—By T. A. Rickard. Cloth, octavo, 690 pages, illustrated. Price 42s. net. New York: John Wiley & Sons; London: Chapman & Hall, Ltd. This book is a compilation of articles appearing in the *Mining and Scientific Press* during the years 1915 to 1920.

Mining Law of West Africa.—Price 15s. net. Published by the Imperial Mineral Resources Bureau.

Sir John Cass Technical Institute.—Syllabus of Classes for Session 1921–2. Issued by the Institute, Jewry Street, Aldgate, London, E.C. 3.

Lead, Zinc, Copper, and Nickel Ores of Scotland. By G. V. Wilson, with contributions by Dr. J. S. Flett. Paper boards, octavo, 160 pages, illustrated. Price 7s. 6d. net. Published by the Geological Survey of Scotland. Reference is made to this book in an editorial in this issue on copper in the Shetland Isles.

The Mutue Fides-Stavoren Tinfields. By Dr. P. A. Wagner. Paper covers, octavo, 200 pages, illustrated. Price 7s. 6d. net. Memoir No. 16 of the Geological Survey of the Union of South Africa.

The Mining Geology of Kookynie, Niagara, and Tampa, in the North Coolgardie Goldfield. By J. T. Jutson. Paper covers, octavo, 100 pages, illustrated. Bulletin No. 78 of the Geological Survey of West Australia.

COMPANY REPORTS

Leeuwpoort Tin Mines.—This company is controlled by the South African Townships Mining and Finance Corporation, and has worked tin mines wo… Waterberg district of the Transvaal since to resum… Irvine Jameson is the manager. The up on th… 1920 shows that 61,982 tons of ore was Firstly, c… that, after the removal of waste, 55,335 (1) There … t to the stamps. The yield of tin and steel tha… was 985 tons, averaging 62% metallic iron, either fce of concentrate brought an income blast-furnace The mining costs were £88,358, … ation charges £23,484. The allowance for development and depreciation written off was £14,990, and the taxes, etc., £6,021. The shareholders received £41,250, being at the rate of 15%. The ore reserve is calculated at 64,488 tons, averaging 2·4% metallic tin, figures not much different from those the year before.

Ropp Tin.—This is the largest producer of tin concentrate on the Bauchi plateau, Nigeria. Edmund Davis is chairman of the company, and the Consolidated Gold Fields of South Africa are the consulting and superintending engineers. The report for 1920 shows that the output of concentrate was 1,017 tons, of which 619 tons was obtained by dredging, 162 tons by ground sluicing, 150 tons by tributing, and 86 tons from other sources. The proceeds from concentrates sold were £52,900, and there are credits of £59,064 for concentrates on hand and in transit. There was a loss on the year's work of £7,595, this position being entirely due to the fall in the price of tin. The proved ground is estimated to contain 10,006 tons of cassiterite. No new ground has been tested during the year. The output during the first half of the current year was 561 tons.

Waihi Grand Junction.—This company has worked a gold mine in the north island of New Zealand, adjoining the Waihi mine, since 1895. Dividends were paid from 1910 to 1918. The report for 1920 shows that 57,450 tons of ore was raised and treated, yielding gold and silver valued at £109,506. The working cost was £130,463, and provision for income tax £4,238. There was in addition an income of £8,005, arising chiefly from interest on investments. The result of the year's work was a loss of £21,016, which, added to the adverse balance of £10,550 brought in from the previous year, makes a total debit balance of £31,566. The ore reserve is estimated at 120,500 tons, as compared with 90,450 tons the year before, but assay-values are not given. The directors do not now publish the mine manager's report, nor do they give details of gold and silver production and the premium received on the gold sold.

Broken Hill Block 14.—The report of this company now issued covers the half-year ended March 31. The mine was reopened at the conclusion of the strike on November 22, but operations were suspended again at the end of December, owing to the unsatisfactory condition of the metal markets. During the short time the mine was being worked 405 tons of carbonate ore, averaging 24·3% lead and 13·8 oz. silver per ton, was mined and delivered to the Associated Smelters at Port Pirie, and 1,201 tons of sulphide ore was raised and sent to the Block 10 joint plant. The accounts show a loss for the half-year of £17,671.

Broken Hill Block 10.—The report now issued covers the half-year ended March 31. The long strike terminated on November 10, and from that date until the end of December some mining was done, while the concentration plant, treating Block 10, Block 14, and Junction ore, ran from November 15 to January 31. The joint treatment of ore from the three mines named included 3,386 tons from Block 10, and 6,234 tons from Block 14 and Junction, making a total of 9,620 tons, averaging 11·5% lead, 9·34% zinc, and 8·89 oz. silver per ton. The lead concentrate won was 1,508 tons, averaging 61·3% lead, 6·5% zinc, and 36·6 oz. silver, and the zinc concentrate 1,718 tons, averaging 45·7% zinc, 7·26% lead, and 13·9 oz. silver. The accounts show a loss for the half-year of £18,800.

The Mining Magazine

EDITORIAL

THE great explosion at the Badische Anilin & Soda Fabrik's works at Oppau points to the danger of the explosives containing ammonium nitrate or of the process by which it is made, and the manufacturers of mining explosives will investigate accordingly. The information available at present is, however, not sufficient to warrant any expression of opinion.

ON October 10 a lecture on the geology of petroleum was given by Sir Frederick Black, president of the Institution of Petroleum Technologists, at the Sir John Cass Technical Institute, Jewry Street, Aldgate. This lecture constituted an introduction to the course on petroleum technology which has this year been added to the curriculum of the Institute. We are glad to see the continual expansion of the Sir John Cass Technical Institute. The lectures and instruction are eminently suited to the requirements of men engaged during the day time, and both technical and non-technical men find the courses of study extremely helpful.

ELSEWHERE in this issue we print an article on the "Characteristics of Cassiterite," by Mr. E. H. Davison, lecturer on economic geology and mineralogy in the Camborne School of Mines. This article may appear to some readers to be rather elementary for a paper like THE MINING MAGAZINE. The fact is, however, that many minerals are continually being mistaken for cassiterite, and vice-versa, so that a concise statement giving the characteristics of all these minerals should prove useful in many quarters. The identification of cassiterite is a subject on which much could be written, and we hope some of our readers will send contributions to our pages giving details of their particular experiences in the field.

THE contempt displayed by politicians and the public for scientists and mining men forms the theme for many paragraphs in this issue. One of those to utter a protest against this treatment is Mr. T. G. Trevor, the Inspector of Mines for the Pretoria District, who in the *South African Journal of Industries* for August appeals to the public to put more faith in the value of the services of the scientific man. As this appeal takes the form of an article appearing in a monthly magazine published by authority of the Minister of Mines and Industries, it is clear that the appeal stands a good chance of being read by the politicians.

WE note with pleasure that *Nature* takes up the cudgels on behalf of Sir Thomas Holland, who has been obliged to resign from the Council of the Viceroy of India under circumstances already known to our readers. Lord Reading's assertion that the Minister of Commerce should have been a lawyer instead of a man of science is one of those legal generalities which create so much havoc in the world of common sense, and the men of science resent it in a body. No doubt the dismissal of Sir Thomas Holland will be brought before Parliament in due course, for this degradation of a competent and sympathetic Minister was a most ill-advised action, especially at the present time, when the future of India is in the balance.

MINING engineers found much to interest them at the Shipping, Engineering, and Machinery Exhibition held at Olympia last month, as will be seen from the brief description printed elsewhere in this issue. One of the features of the Exhibition was the holding of special receptions for various classes of engineers, on which occasions lectures were delivered on the subjects of greatest novelty in each particular line. One evening was set apart to the Institution of Mining Engineers and the Institution of Mining and Metallurgy, and the social intercourse and the opportunity for inspecting the exhibits in congenial company were greatly appreciated. A lecture and demonstration was given by Professor Edwin Edser, who explained the principles of froth flotation as applied more especially to the saving of waste coal. When future exhibitions of this class are held we hope to see the makers of machinery used at mines more widely represented. As a matter of fact we believe that at the next exhibition efforts will be made to secure a representative show of modern types of mining machinery of all kinds.

PARTICULARS are to hand of another shaft-sinking record. At the Chief Consolidated mine, in the Tintic district, Utah, the Water Lily vertical shaft was sunk 427½ ft. during the 31 days from July 15 to August 15. The first 367 ft. passed through a porphyry formation, and the last 60 ft. through a moderately hard close-grained limestone. The shaft has three compartments, each measuring 4 ft. 4 in. by 4 ft. 6 in. The surface equipment consists of two small hoists and two air-compressors operated electrically. Hoisting was done through two compartments. Timbering was done as the work proceeded by means of a suspended steel bulkhead hung from each last set, so that drilling and hoisting could be done continuously. The drill employed was the Waugh Clipper, and the average number of holes drilled each round was 23·9. The particulars supplied do not include the depths below surface of the start and finish of this trial. The previous 31 days' record was the 310 ft. sunk at the Crown Mines No. 15 circular shaft in July, 1919. Here the shaft was 21½ ft. in diameter, and the hoisting depth averaged 2,150 ft., while the rock was hard Rand quartzite and the drills employed were Holman sinkers. These shaft-sinking competitions are not official, and there is no handicapping as regards rock, energy of the crew, or capability of the drills employed, so all we can do is to congratulate the respective crews for getting a move on.

British Coal-Mining

There are signs that all sections of the community are now taking a more reasonable attitude with regard to coal-mining, the industry on which the prosperity of this country depends. Both the owners and the workers are listening more readily to the advice of well-informed men of independent position. Perhaps the most notable pronouncements of this sort were made by Sir John Cadman and Dr. J. S. Haldane at the recent meeting of the Institution of Mining Engineers. Sir John, in his presidential address, spoke in frank and unmistakable language of the causes of the present unsatisfactory condition of the industry. He showed that, whereas in 1900 the output of coal was 291 tons per man employed, the figure had fallen to 183 tons in 1920. There are several factors which may have contributed to this fall. The thicker and more accessible seams are gradually being exhausted, and thinner seams and seams at greater distances from the shafts are being worked. Some people also maintain that the mines are overmanned, and that the surplus force does not add to the productive capacity of the collieries. It may be, as Sir John said, that all British industry has been passing through one of those lazy fits that recur from time to time. But all these are held by him as not affording the real reason. In his view over-legislation is the cause which operates the most effectively in restricting output. During the last twenty years coal-mining has been subjected to a degree of political and legislative interference without parallel in any other industry. These enactments have so circumscribed the initiative of both masters and men in matters that might have been much better left to their own discretion, and have so fettered their freedom of action and choice as to stifle their natural spirit of energy and enterprise. The restrictions and regulations were mostly imposed by outside authorities little conversant with the matters in hand, and the legislation has been fussy and ill-conceived; the result of the regulations has been the virtual abolition of personal responsibility and of co-operation between managers and men. In fact, hasty and inappropriate laws have diminished the output, and at the same time have not increased the safety of working. There are really so many regulations that the time of the managers and men is taken up chiefly in following them and signing forms, and personal initiative in mining practice has been stifled. In Sir John's words, what coal-mining in Great Britain most needs is a respite from the well-meant but bungling attentions of Parliament.

In the speeches following the delivery of Sir John Cadman's address, Dr. J. S. Haldane spoke in his capacity as adviser on improvements in underground conditions, and he voiced the general complaint of scientific men that their advice is often ignored, and that if it is accepted it is usually applied by people who have no knowledge of the subject. His contention is that, if certain recommendations of a scientific committee are agreed to, the advice of that committee as to the methods of carrying them out in practice should also be taken. He showed that in many cases scientific recommendations have been quite wrongly applied. Even if the committee particularly requested that no legislation should be under-

taken without further reference to them, the Government officials continue in their usual course. Dr. Haldane instanced cases where his own recommendations had been applied in such a way that little good has ensued; in fact, the regulations founded on them only served to tie the men up in such a way that they did not know which way to move. It is to be hoped that the protests uttered by two such high authorities as Sir John Cadman and Dr. Haldane will have some effect on the Government; they will certainly be accepted by the coal industry and all associated with or dependent on it.

Arizona Copper

For two years or more the directors of the Arizona Copper Company have been in negotiation with the Phelps-Dodge Corporation with a view to the sale of the properties to the latter. After much delay terms have been agreed and placed before shareholders. It may be said at once that the terms have been considered disappointing, and that the shares have suffered considerably on the market accordingly. We believe, however, that this dissatisfaction is not well founded, and that shareholders will eventually find they have a sound and satisfactory investment. Briefly, the purchase price paid by the Corporation is 50,000 shares of $100 each, to rank equally with shares that have received an average return of 18% per annum during the last twelve years. The present issued capital of the Corporation is 450,000 shares of $100 each, so that the Arizona Copper Company will hold just one-tenth of the shares of the Corporation. The issued capital of the Arizona Copper Company is £703,984, of which rather more than half is represented by ordinary shares. During the last dozen years the dividends on the ordinary shares have averaged 50%, but owing to the severe collapse of the copper market no profit was made in 1920, and the mine was closed in May of this year, along with many other American copper mines. At first sight the times may not appear auspicious for a sale of the properties, and that a company which has to find means for financing its present losses and also has a prospect of having to raise further capital for the exploitation of the lower grade ore is not exactly a free agent in the deal. But the Phelps-Dodge Corporation is not an organization that relies on the big stick policy, or holds a pistol to the parties with whom it negotiates; moreover, it does not keep an eye and a half on the Stock Exchange, and only half on its proper business. The Corporation and its predecessor, Phelps, Dodge & Co., have a fine record for technical ability and business probity, and any agreement to which it sets its seal is likely to prove a fair one. Its commanding position in the copper world was largely built up by the late Dr. James Douglas, whose high character was proverbial. The shares are almost entirely held privately by people who value them for the income they yield, and they seldom change hands. Shareholders in the Arizona Copper Company must learn to adopt the same attitude. It is clear, on the other hand, that some means of valuing or selling holdings on this side is desirable, and for this reason the Phelps-Dodge shares will not be distributed among Arizona Copper Company shareholders, but will be held by the latter company, which will thus become a holding instead of an operating company.

The two companies began active work in Arizona at about the same time, the Arizona Copper Company in the Clifton-Morenci district, which was the first copper-mining region to be developed in the South-Western States. The discoveries leading to the commencement of a new industry happened about 1875, but it was not until the early eighties that active work was taken in hand. In those days rich oxidized ores in a limestone gangue were treated, and the smelting experiences on this class of ores formed an interesting incident in the history of the metallurgy of copper. The Corporation began work at Bisbee, and later acquired the Detroit property at Morenci, the Globe and Old Dominion at Globe, the Moctezuma group over the border in Sonora, and the Bunker Hill at Tombstone, while smelting operations have been conducted at Bisbee, Douglas, Globe, and Morenci. The ores treated in the Clifton-Morenci district have gradually become of lower and lower grade, and the methods of mining, concentration, and smelting have had to be continually modified. To the Arizona Copper Company belongs the credit of having first treated the so-called "disseminated" or "porphyry" type of deposit, long before Utah Consolidated and Miami were heard of. The Arizona Copper was also the first company to establish leaching plants for the oxidized ores. It is worthy of record

that a substantial proportion of the ore-minerals now mined are oxidized, consisting of malachite, with smaller amounts of cuprite, chrysocolla, and other compounds, but the chief mineral of the ores is chalcocite. At the present time the Arizona Copper mines and the Detroit mine are showing signs that another entire rearrangement of the mining and concentration methods will have to be undertaken so as to treat the vast reserves of ore of a still lower grade. The capital sum involved will probably come to millions of pounds, and the Corporation is better able to provide the funds. Another point in favour of the Corporation undertaking this work is that if the money were provided in this country a considerable loss would be incurred in sending it to the United States with the dollar exchange in its present position. The Corporation's interests in the Clifton-Morenci district are far from being the most important of its possessions. The Copper Queen and the Moctezuma are big producers of copper, the Tombstone mines yield lead, silver, and gold, and the Corporation also operates coal mines at Stag Canon. The Arizona Copper shareholders may therefore be congratulated on securing a permanent interest in a company which has such a wide ramification of possessions. We cannot do better for a peroration than quote the *Copper Handbook*, which says: "Phelps Dodge is one of the few new companies in the copper-mining industry that is under-capitalized rather than over-capitalized, and this is but a detail in a general business policy that, while thoroughly progressive and abreast with the times, retains the fundamentally sound and conservative policies developed by the old firm in nearly a century of honourable and markedly successful business life."

The Cornish Crisis

Two months ago we made an appeal for the Cornish tin-miner, workless and threatened with starvation owing to the stoppage of the industry on which he depends for a living. Unfortunately the position is rapidly becoming more acute, and the outlook for the winter is undoubtedly very serious. The unemployment dole has automatically ceased, and the distressed are officially thrown on the rates, which are entirely inadequate. Cornishmen are earnestly seeking some satisfactory solution of the difficulty. They are generously raising funds to afford temporary relief, but it is universally held that charity cannot be effective for long, as the purses of the givers are not bottomless in these days, and also that it is of little use to wait for the market in tin to revive. Thus the Cornishmen's endeavours are twofold, one dealing with the raising of funds to afford temporary relief, and the other to find the men some work that will benefit themselves and the county.

As we mentioned in the previous article, the Distress Fund for the Camborne-Redruth Area is doing excellent work. Mr. F. D. Bain, the tin-smelter, is the treasurer of the fund, and the Reverend W. A. Bryant is the active organizer. Mention should also be made of the valuable assistance given to the committee by Mr. Herbert Thomas, of the *Cornish Post*, who has obtained many subscriptions from Cornishmen abroad. There is a separate Distress Fund at St. Just, of which Mr. Richard Nicholas is treasurer, and substantial sums have been contributed to it by the residents of Penzance. Many people are desirous that St. Just should be included in the other area, and that the Lord Lieutenant should be thus enabled to constitute a county fund. Such a rearrangement would greatly add to the influence of the Cornish appeals.

The police, too, are taking an active part in the relief of distress. The Chief Constable of Cornwall, Lieut.-Col. H. B. Protheroe Smith, has issued an appeal for his "Cornish Tin Miners' Relief Fund," and as it clearly reflects the present position and the pressing necessity for help we quote the appeal herewith. Writing from the Chief Constable's office at Bodmin, he says :—

"Owing to the high price of coal during the past few months and previously, and the low price of tin, all the tin mines in Cornwall have been closed down for several months. Of the many men out there are 3,000 who, from the end of September, receive no unemployment dole at all, and it is estimated that they have about 9,000 dependents. About 600 of the younger men emigrated, until emigration opportunities for tin miners ceased. These men and their forefathers have always been miners. Many of them are men of 45 to 55 years of age, with large families. Of the amount which has been raised for them by means of this fund, and is now almost expended, as much as possible has been spent in payment for relief work, and as little as possible in doles. At present we have only sufficient to last until the middle

of October. Food depots have been opened and hundreds of parcels have been given away weekly. The men want work and not doles, and the object of the fund is to keep the men employed on relief work until the mines reopen, and to procure food for the women and children, and also coal. There is a tremendous amount of privation. I will only quote the most recent case which was reported to me last week, and is a typical case of where help is needed. A man, his wife, and nine children, no unemployment pay, sole income 15s. a week from the eldest son, aged 16, except what they get from the Relief Fund.

"I am trying to get all the financial assistance I can for the miners, because: (1) these men never lost a single day's work through being on strike; (2) while the mines were working, in some mines they voluntarily gave up 20% of their pay to try and keep them going; (3) the mines received no subsidy, and no inflated bonus was ever asked for or received by the men during the war; (4) their maximum pay (except the contract men) was 50s., minimum 37s. per week; (5) their conduct up to the present has been exemplary, in fact, wonderful.

"The Cornish Police have voluntarily subscribed £270 (an average of £1 per head) during the last four months, and are still subscribing, and I am collecting clothing through the police all over the county. The Prince of Wales, Duke of Cornwall, has given £300 to the Relief Fund.

"I know the great distress all over the country, but in view of the foregoing, especially where so many women and children are concerned, who have no means of support for the present, very little food, poor clothing, and no coal, I should be very grateful if you could help me with a donation to the fund I am trying to raise, and could mention it to any of your friends."

We endorse this appeal, and have already sent a contribution to the fund. Perhaps some of our readers will follow this example. Colonel Protheroe Smith is a kind-hearted man, as are also Deputy Chief Banfield and Superintendent Smale, who are associated with him in this work. The county police are deservedly popular, for they are tactful and sympathetic and do everything to help the miners and to keep them in good temper and in a reasonable frame of mind. In fact the police in Cornwall and throughout the kingdom are the sincere and discriminating friends of the poor and of those in trouble.

So much for present relief, but the greater question emerges as to how to provide these men with permanent work. In the first place it may be asked whether there is any chance of the mines being reopened. Under ordinary circumstances the answer would be that economic conditions offer little hope for any immediate resumption of work. By those desirous of adopting a more active policy it has been suggested that the mining companies should follow the example of some of the iron-masters and resume operations without any hope of a profit, trusting that the improvement in trade so confidently expected will put them right in the long run. Most of the tin-mining companies, however, are too poor to stand the financial strain involved by such a policy, and the two companies most likely to be able to adopt the policy are at present worried with water and shaft troubles. Another suggestion would be to ask the Government to guarantee to the companies sufficient financial aid to meet their working costs. This proposal is on the same lines as that brought forward a year or more ago to the effect that doles should be diverted to the mines with this desirable object in view. Though the Government refused to listen then, there is reason to hope that with the altered financial condition of the country some such arrangement might receive consideration. On the other hand, some of the mining companies would not take kindly to Government interference, for such co-partnership has proved expensive and irritating in other quarters. If the miners cannot be helped by the reopening of the mines, the only alternative appears to be to start works of public utility. There are at present many such schemes suggested for Cornwall. One that has recently been promulgated seeks to provide for a new drainage system at St. Just. But here, again, the question of finance introduces difficulties, for the Government, the counties, and the boroughs are already so saddled with debts and financial commitments that the raising of the necessary funds will not be an easy matter. Nevertheless, it is the scheme that is most likely to obtain the support of the Government, and before long it is probable that some public announcement will be made on the subject on these lines. Works of this character can, of course, only be considered as temporary expedients and palliatives, and Cornishmen will have to continue to discuss the ways and means of

reopening the mines, or in other ways of providing profitable industrial occupation for those at present deprived of their means of livelihood.

The British Association

After passing through a difficult period of its existence owing to scientists having devoted themselves to the study of war problems and laying on one side for the time the public exposition of new truths and theories, the British Association has gained its old footing this year, and the meeting held in Edinburgh last month was one of the most successful recorded during its existence of ninety years. Being free from war worries the scientists were able to devote thought to the reorganization of the methods of conducting the meetings and to the introduction of improvements in the means of presenting information and raising useful discussion. Those who attended the Edinburgh meeting are unanimous in their praise of the executive, and in expressing the opinion that the British Association is itself again.

In the midst of the prodigal spread of lectures, papers, and discussions, there stood out three which drew general attention and constituted the important features of the meeting. These were concerned with the release of atomic energy, the age of the earth, and isotopes, three subjects which are intimately connected. Readers of the MAGAZINE are fairly familiar with the first two subjects, but probably know little or nothing of isotopes. This word was coined to represent elements possessing the same chemical characteristics and inseparable by chemical means, but having different atomic weights. The name is derived from the fact that they occupy the "same place" in the periodic series of Mendeleeff. From the researches of a number of chemists, of whom Professor F. W. Aston is the chief, it is believed that many elements as known to-day are a mixture of isotopes, a supposition which explains why their atomic weights are not whole numbers. Thus chlorine, whose atomic weight is 35·46, is held to be a mixture of two elements having the atomic weights of 35 and 37. The isotopes making up an element as we know it are quite inseparable by any chemical means, and their existence would only be based on supposition if there were no evidence of the existence of one by itself and freed from its fellow isotopes. It is here that the subject of the release of atomic energy and the breakdown of the atom is connected with that of isotopes, as mentioned above. It has been found in the course of study of radio-activity that when thorium and uranium undergo radio-active disintegration they assume the chemical characteristics of lead and its position in the periodic series, but differ from it in atomic weight. Lead prepared by any chemical method is taken to be a mixture of isotopes that travel together through all current reactions, while lead obtained by the destruction of the uranium atom is a new creation and consists of only one of the isotopes of lead.

As regards the breakdown of the atom and the resulting release of atomic energy, the scientists concerned have not got further than demonstrating this physical fact in the case of radium, and no means of generation of power on a greater scale has as yet been found, so for the present this ultimate source of power need not be considered in these pages. But mining men must keep this future possibility at the back of their heads and thus be aware of the progress of science as it may affect them.

The other subject discussed at Edinburgh to which we have made reference relates to the age of the earth. Lord Kelvin, before the days of radio-activity, had estimated the period during which life could have existed on the earth at a maximum of twenty million years, basing his calculation on the rate of cooling. During recent years it has been discovered that the disintegration of uranium has provided an internal source of heat which has caused this rate of cooling to be far slower than was known to Lord Kelvin. Calculations based on the change of uranium to lead indicate that the figure would be more nearly a thousand million years. There is considerable difference of opinion as to whether the unit of uranium time has been constant or not, and in particular Professor Sollas has shown from a study of bombardment rings in the mica of granite that the disintegration of uranium must have been more rapid in the earlier stages of the world's history.

In all the three branches of the subjects here described the speculations are daring in their conception, but as they are based on undisputed evidence they deserve recognition and consideration. The only point of reservation is how far the reasoning is affected by other factors known or unknown to us at present.

REVIEW OF MINING

Introduction.—The state of trade in this country continues to be bad, and the general position is now being seriously considered by the Government. Everybody knows by now that the remedy lies in harder work for smaller pay, diminution of profiteering on the part of distributors, and a drastic reduction of public expenditure. The only difficulty is to get people to act on this principle. In the meantime mining of all sorts is in a very depressed condition.

Transvaal.—The leading houses continue to discuss the economic situation, more particularly with regard to the management of labour. Consideration is also being given to the engineering side of the problem, for it is generally felt that many improvements could be introduced in mining and metallurgical practice independently of the labour question. It can hardly be denied that the Rand has lagged behind in technical progress. One cause of this backwardness is undoubtedly due to the fact that the control in these matters is far too tightly held by the boards of directors, and that the engineers do not have the free hand they should.

Considerable interest has been aroused by the publication of a cable to the effect that Springs Mines is adopting an all-sliming process. The cable says: "Directors have decided in extending reduction plant to discard stamp battery and plate amalgamation, and adopt all-sliming of ore and direct cyanide treatment. Decision come to as a result of metallurgical experiments, and will result in reduced capital expenditure, probably saving operating costs, increased extraction gold contents." As far as any written communication on the subject is concerned, the only information we have received relates to the elimination of stamps. During recent years it has been the tendency to send coarser material to the tube-mills than formerly, and the openings in the battery screens have been gradually made larger. They are so large nowadays as to make stamping almost supererogatory, seeing that the modern crushers will supply a product suitable for the tube-mill. Thus it is now proposed to eliminate the stamp-mill and the battery amalgamating plates. The other two questions remaining for consideration are, first, the elimination also of amalgamation below the tube-mills, and, second, the abandonment of classification into sand and slime, the comminution of all the ore to slime, and the treatment of the whole in agitators. In this all-sliming method the cyanide solutions would be introduced in the tube-mills. Presumably the cable means that amalgamation is entirely eliminated, and that there is to be only one product for cyaniding. We postpone further discussion until complete information arrives.

The reports of those companies of the Central Mining-Rand Mines group whose financial years end with June 30 have been issued this month. Of these, New Modderfontein is the most important. Here the tonnage milled and the profit are both highest on record, the figures being 1,083,000 tons, as compared with 968,500 tons the year before, and £1,699,052, as compared with £1,493,845. Of the profit no less than £751,427 accrued from premium. The grade of the ore milled was half a pennyweight lower than the previous year, and the cost per ton was up 1s. 6d. An important feature of the development work was the discovery of ore averaging 9·7 dwt. over a large stoping width, 82 inches, in the area west of No. 2 shaft between the 12th and 13th levels. No ore of this character has hitherto been discovered in this section of the mine.

The Custodian of Ex-Enemy Property is visiting London again in connexion with the disposal of the shares under his control in the gold mining and other companies in South Africa, and it is hoped that a scheme will be settled before long between the British and Union Governments.

Rhodesia.—The output of gold during August was returned at 53,200 oz., as compared with 51,564 oz. in July and 48,740 oz. in August last year. The other returns from Southern Rhodesia for August were: Silver, 14,609 oz.; coal, 51,088 tons; chrome ore, 2,676 tons; copper, 263 tons; asbestos, 1,212 tons; arsenic, 10 tons; mica, 3 tons; diamonds, 9 carats.

It will be remembered that the Planet-Arcturus group of gold mines was reopened a short time ago by the parent company, the Gold Fields Rhodesian Development Co., with the object of repaying the cash advances previously made. It turns out now that the costs are higher than expected, so the Gold Fields company has determined to work the higher grade ore only. The reserve at June 30 was 251,034 tons, averaging about 11·8 dwt., but a large

amount of lower-grade ore has now been omitted from the estimate, and the new figures are 139,600 tons, averaging 13·27 dwt. Only this higher-grade ore is now being worked.

Kenya.—The Magadi Soda venture is still hampered in its progress by various economic factors, and the financial result for 1920 was a debit of £159,326, bringing the total adverse balance to £357,000. At first sight it might be thought easy to market these vast deposits of natural soda, but their development was blocked during the war in many ways, and then the trade opposition is powerful. Those who are acquainted with the chemical business know how hard it is for a new-comer to secure a market even for a commodity in universal demand. The Magadi enterprise is in the hands of strong people, the Shell and the Central Mining groups, and they will surely win through eventually. Production and sales started last year, and have increased slowly and steadily since.

Nigeria.—In June last it was mentioned that the Naraguta Tin Mines was developing alluvial gold prospects in the Birnin Gwari and Kano regions. The necessary pumping and crushing plants have since been acquired, and we are informed that Mr. Clyde Allen is leaving London for Nigeria about the middle of next month for the purpose of organizing a comprehensive campaign of exploration and development.

Australia.—It is announced that the Electrolytic Zinc Company of Australasia, whose works are at Risdon, Tasmania, has made a contract with the British Government to take 750,000 tons of zinc concentrates over a period of years. Presumably this contract will help to relieve the British Government of part of its burden, but further details are necessary before the exact influence of the contract can be ascertained. In the meantime the stocks of this product are accumulating at an increasing rate, and in addition the Broken Hill Proprietary has decided to resume production of this article. The following table gives in actual cash the Government disbursements to the mines during the five months April to August :—

	Tons	£
April .	. 11,943	53,743
May .	. 14,085	63,382
June .	. 16,677	75,046
July .	. 17,758	79,911
August	. 22,418	100,881
Totals	. 82,881	372,963

The Gold Producers' Association of Australia report that during July 89,888 oz. of standard gold was sold, realizing an average net price of 101s. 9d. per oz., which is equal to 112s. 9d. per oz. fine. The net premium received during the months January to June was £444,636, which represents 21s. 10d. per oz. fine on the gold sold. Of this amount £144,544 was distributed among members of the association on May 30, and the balance on August 25.

At the Sons of Gwalia mine the plant for the re-treatment of sand and slime was started on September 20. It will be remembered that the mill was destroyed by fire early this year. The present announcement indicates a resumption of gold production. The new main plant will be ready later.

A cable message announces the closing-down of the Mount Bischoff tin mine in Tasmania, owing to the unfavourable conditions in the tin market. For some time this celebrated mine has been yielding only low-grade ores, but there is no reason to think that the closing is final, for the last fortnightly reports to hand by mail refer to increased provision for roasting the pyritic ores.

A serious explosion occurred last month at the Mount Mulligan colliery, North Queensland, operated by the Chillagoe Company, when over fifty men lost their lives. The disaster is all the more to be deplored because the coal and coke are relied on for many metallurgical operations in this region. Particulars of this coalfield were given in our issue of February, 1918.

India.—The scheme for raising further capital for Champion Reef has now been put before shareholders. The capital of the present company is £260,000, in shares of 2s. 6d. each ; a new company is to be formed with the same nominal capital, but divided into shares of 10s. each, of which one will be given credited as 4s. paid for every four in the old company. This may seem a very drastic reconstruction, but it must be remembered that most of the shares in the company were issued at high premiums, and that holders have paid far above par for their shares and have received big dividends for many years. The output of gold has fallen considerably lately, so that it has been necessary to draw on the reserve fund for expenditure on capital account, usually met out of revenue, and also restrict the amount of development. The funds now raised are required for further development, and for

additional expenditure to provide for deeper operations.

At the Balaghat mine the lode has been intersected on the 1,200 ft. level south where the assay-value of the ore is 15 dwt. gold per ton over a width of 4 ft. This is the lowest level in the mine.

The Indo-Burma Oilfields, Ltd., has made an issue of £250,000 debentures for the purpose of developing its properties. The company was formed last year for the purpose of acquiring property in the Yenangyaung oilfield, particularly at Yenanma, Padaukpin, and Okpon. Col. H. H. Johnson and Mr. S. C. Sampson are the engineers in charge. Co-operative arrangements have been made with the Yomah Oil Company, of which Dr. Arthur Holmes is the manager, for drilling and also for refining.

Cornwall.—A second appeal for aid for the out-of-work tin miners is made in another part of this issue. This appeal is now being actively backed by many of the leading London daily papers. We do not hear of any likelihood of mining being resumed anywhere at present.

No further news is to hand with regard to the position at East Pool and South Crofty, but there appears to be some prospect that the two companies will not go their own ways independently, as might be inferred from the announcement by East Pool, recorded in our last issue. It would not be advisable for us to say more than this at present.

Lead and Zinc in Britain.—A more reasonable attitude is now being shown by the unions who control the doings of the lead miners, and it may be possible to resume work here and there. At Wanlockhead, in Dumfries, the men have signified their willingness to try the owners' terms. It is not likely that any zinc will be mined anywhere in Britain, for the demand for British concentrates has vanished. As regards the reopening of zinc smelters, the Villiers works at Swansea is being started on half capacity as a trial, but none of the other companies shows any inclination for resumption.

Canada.—A circular has been issued by the Kirkland Lake Proprietary Company, which announces that the continuation of the faulted No. 2 lode on the Tough Oakes has been found in a cross-cut from the 500 ft. level; also that a cross-cut driven since on the 300 ft. level has intersected the upthrown lode. This part of the lode is in the Burnside property, and future development will be done from the Burnside No. 3 shaft. Mr. W. H. Goodchild is now making a geological examination.

Colombia.—The Colombian Mining and Exploration Company has issued a statement to the effect that the new mill for the treatment of the Marmato gold ores, as outlined in September of last year, is in course of construction. It is hoped to have the first unit, which will be of a capacity of 3,000 tons per month, ready by the end of January, and the remainder, bringing the capacity to 10,000 tons, by the end of March.

Bolivia.—As already recorded in these columns, the Aramayo Francke Mines, Ltd., has changed its domicile to Switzerland, where the company is now known as the Compagnie Aramayo de Mines en Bolivie. The completion of the transfer of the property was effected on December 23, 1920. The Swiss company now issues a report for 1920, and the accounts are in Swiss francs. The market here converts the figures into pounds at 22·50 francs per pound. Thus the profits are given at £234,500, as against £663,900 for the previous period, 19 months ended December 31, 1919. The dividends distributed were £119,440, being at the rate of 20%, as compared with £179,127, or 30% for the previous period. The balance, which is a large one, is kept in hand, so that the company shall preserve its strong position in these doubtful times.

Portugal.—The directors of Mason & Barry, Ltd., the company which has worked the San Domingos pyrites mines at Mertola for fifty years, announce that negotiations are in hand that may lead to the sale of the properties, but no details of any sort are given.

Czecho-Slovakia. — The Imperial and Foreign Corporation, of which Mr. Herbert Guedalla is the head, has become interested in the Joachimsthal uranium-radium mines, in so far as the marketing of the products is concerned. For the purpose of conducting the business the corporation and the Czecho-Slovak Government have formed a company called the Czecho-Slovak Company for the Exploitation of Radium. A large consignment of radium bromide has already arrived in this country, and the best way of deriving an income from it is now being devised. We have not yet heard of any pressman alleging that the presence of this radium accounts for the abnormally hot weather now being enjoyed in London.

TRINIDAD:

A REVIEW OF ITS GEOLOGY AND OIL RESOURCES

By HENRY B. MILNER, M.A., D.I.C., F.G.S.
Lecturer in Oil Technology, Royal School of Mines

In the following article the author summarizes our present knowledge of the geology of the Island of Trinidad, with special reference to the mode of occurrence and storage of its oil. An account is given of the progress of development of the petroleum resources, and some of the more important technical difficulties encountered during oil exploration in the Island are discussed.

(*Concluded from September issue, p.* 148.)

ECONOMICS.

The geological history of Trinidad during Tertiary times embraces three quite distinct phases of sedimentation with which the occurrence of petroleum in the island is intimately related. It has been found that for the main oil-producing region in the south, two petroliferous groups of strata are recognizable, a lower and an upper; the lower corresponds to the Eocene-Oligocene (in part) phase, the two together sometimes known as Palæogene, and represents a period of marine transgression in which essentially marine sediments were laid down in the north (Naparima area), and shallower water deposits in the south (Siparia, Erin, etc.). The upper group corresponds to the late Oligocene and Miocene (in part) phase, during which the pre-existing ocean basin was rapidly filled up by excessive sedimentation, producing abundant arenaceous material and a marked absence of calcareous facies, characteristic of the lower group in the Naparima area. The third phase constituted by the late Miocene and Pliocene epoch was a period of orogenic movement, and the uplift occasioned a still further shallowing of the sea, with concomitant production of estuarine and even terrestrial deposits, now represented by the Moruga series; a certain amount of oil occurs in association with this series, but it has probably all migrated across the unconformity from the underlying Naparima beds, the uppermost beds of which constitute the main oil horizons now being tapped. The lower oil-bearing group is not so well known on account of the great depths at which the oil-sands often lie; further reference will be made to this ultimately. With regard to oil production from the Moruga beds, it is important to remember that we are here dealing with beds laid down subsequent to the main Tertiary folding of the region (Middle Miocene), and whose relationship to the underlying series is one of marked unconformability; in consequence, production from wells put down entirely in Moruga beds may be, and often is, of a sporadic nature.

The surface indications of petroleum are extremely numerous in the island; these include the usual oil and gas seeps, mud-volcanoes, asphaltic deposits such as the famous Pitch Lake, and manjak veins. Oil seeps occur very frequently, as for example at Lizard Springs, La Brea, along the Vance River, and at Point Ligoure. Mud-volcanoes are also widely distributed, and they often have a special significance. As in other countries, two main types exist, the simple and the compound; the former consists of a single cone commonly attaining as much as 20 ft. or more in diameter at the base; an exceptional example of this type is seen in Columbia Estate, ward of Cedros, and is known as the "Columbia Chimney," in which the crater alone is 150 yards in diameter, according to Cunningham Craig.[21] The compound type is made up of a series of overlapping smaller cones, varying from a few inches to two or three feet in diameter, these often initiated on the slopes of a much larger simple cone; an example of this is the "Devil's Woodyard" near Princes Town. Other well-known examples of mud-volcanoes in Trinidad are the "Chemin de Diable," south coast of the island, and those at Galfa Point and Islot Point. Their distribution is frequently in a definite direction, corresponding to the trend of important fracture lines; such lines are developed as a result of anticlinal flawing and faulting, particularly in pitching structures. On this account the existence of mud-volcanoes is to many a warning not to drill rather than a good indication, since it pre-supposes fracture and escape of oil, rather than subterranean storage.

Of the solid or semi-solid asphaltic indications, no finer example exists than the famous Pitch Lake at La Brea (Fig. 4*a*). This has an area of about 137 acres and consists of an emulsion of bitumen, sand, and water, solid at the surface, but becoming soft and

viscous in depth, and also in the central parts of the lake. Its maximum thickness is 135 ft., but it shallows considerably towards the margin; the estimated amount of asphalt present is about nine million tons, and notwithstanding the quantity of material already removed, the level of the lake has only sunk about 8 ft., due to the fact that the rate of influx of fluid asphalt beneath tends to counterbalance the amount removed from the surface. Superficially the deposit exhibits the formation of broad folds on a large scale, due to constant motion of material from centre to periphery (Fig. 4*b*); water collects in the troughs of these folds and gas is frequently

Fig. 4a. Plan of Pitch Lake, La Brea.

seen bubbling through it, which on analysis proves to be a mixture of methane, carbon dioxide, hydrogen, and water.[22] Several "islands" composed of sandy cover rock occur in the lake, on which shrubs and small trees thrive; these islands are in slow but continual movement from point to point over the surface of the asphalt, dependent on the motion of the latter.

The methods employed in mining the deposit are quite simple; the asphalt is hand dug, loaded on to trolleys actuated by cable along a rail track (which can be easily shifted as work progresses and also when sinkage occurs), carried by inclined cable for nearly a mile to the wharf, where it is tipped into steamers for export. In 1916, 131,099 long tons of this lake asphalt were exported, of which 13,380 tons went to Europe and 117,719 tons to the United States. Shipments in 1918 and 1919 amounted to 74,504 and 93,951 tons respectively.

Abraham gives the following analysis of the crude material from the centre of the lake[23]:—

Water and Gas volatilized at 100° C.	29·0
Asphalt soluble in carbon bisulphide	39·0
Asphalt absorbed by mineral matter	0·3
Mineral matter on ignition	27·2
Water of hydration in mineral matter	4·3
Total	99·8

Further, after pulverizing and drying to constant weight, analysis gave the following results:—

Asphalt soluble in carbon bisulphide	55·0
Free mineral matter	35·5
Water of hydration, etc.	9·7
Total	100·2

Refining the crude material consists in heating it to 160° C. to drive off water and small amount of volatile constituents; thus purified, the asphalt has a jet-black colour, a somewhat dull lustre, marked conchoidal fracture, and a specific gravity of 1·41 (varies slightly).

The constant motion of this lake asphalt referred to above tends to cause its movement downhill towards the sea, the lake being 138 ft. above sea-level; this results in the production of a large stream of "land asphalt" (Fig. 4a), different in composition from the lake deposit and varying with duration of exposure to atmospheric weathering. This land asphalt is also typically solid at the surface and three varieties are known locally, "cheese pitch," "iron pitch," and "cokey pitch"; the first is characterized by the development of gas cavities, giving it a gruyère-like appearance; the iron pitch is exceedingly hard as a result of continual weathering, and the cokey facies is the product due to carbonization by local

[22] H. Abraham, Asphalts and Allied Substances, 1918, pp. 108–15.

[23] H. Abraham, op. cit., and references there quoted. See also Clifford Richardson, Proc. Am. Soc. Testing Materials, 1906, 6, p. 509, also Modern Asphalt Pavement, 1908, p. 176. Analyses were also given by P. Carmody in his paper on "Trinidad as a Key to the Origin of Petroleum." See footnote (1).

shrub fires, etc. This land asphalt differs from the lake asphalt in containing no gas or water, a higher percentage of mineral matter, and a lesser percentage of volatile constituents.

Besides these lake and land asphalts just described, there are deposits of manjak in the island, mainly found as veins and fissures in the Tertiary rocks of the San Fernando area, and elsewhere; it occurs in sufficient quantity in Trinidad to make its exploitation worth while, and is mined especially at the Marabella and Vista Bella mines. Carmody has given the results of several analyses made on this material, and these show a fluctuation of between 84% and 95% of pure bitumen.[24]

Thus the lake asphalt and the manjak constitute the principal solid forms of petroleum in the island; ozokerite, the natural paraffin wax, though reported from Trinidad, seems to be of very doubtful occurrence there.

Geological Age.	*Horizon.*	*Remarks.*
4. Pliocene (Up. Tertiary).	Moruga Series, "La Brea Oil-sand."	Migrated oil. Heavy, Asphaltic base. Sulphurous. S.G., 0·950, average.
3. Miocene (Mid. Tertiary).	Naparima Series, "Rio Blanco Oil-sand" or Upper Oil Group.	Asphaltic oil. Low sulphur content. S.G., 0·908, average. Chief producing horizon.
2. Palæogene (Lr. Tertiary).	Galeota sands, Lizard sands or Lower Oil group; divisible into two, an upper and a lower Oil-sand.	High grade light oil. S.G., 0·840, average.
1. ? Cretaceous.	(Tabaquite Oil-field, Central Range).	Paraffin base oil. S.G., 0·796.

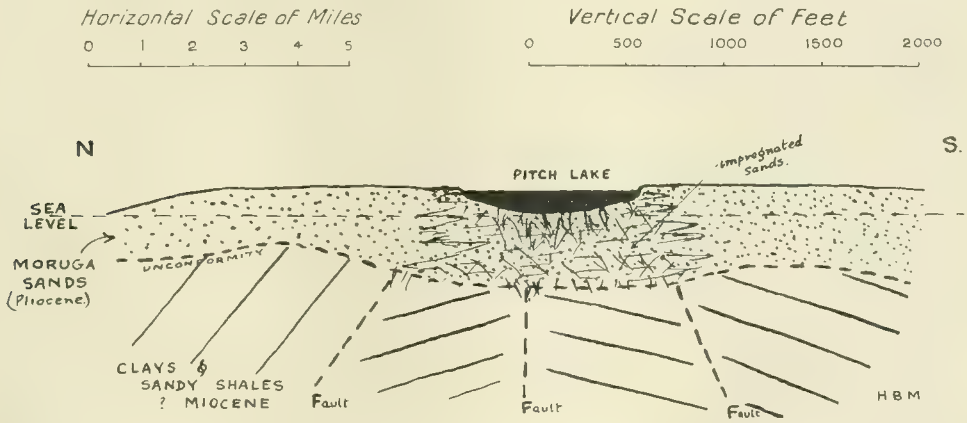

Fig 4 (*b*) Section across Pitch Lake, La Brea
(Based on Wall and Sawkins, and Others.)

Passing now to the oil itself, reference has already been made to the principal stratigraphical horizons from which it is obtainable; we may summarize these as follows:—

Generally speaking, a heavy asphaltic fuel-oil is characteristic of the island, and is obtained chiefly from the Upper Oil group; paraffin and mixed base oils also occur. Carmody has given details of several analyses of liquid and semi-liquid oils from Trinidad, in which the specific gravities of various samples range from 0·796 as at Tabaquite, to 0·977 as at Fyzabad.[24]

With regard to the above horizons, the Tabaquite oil is usually supposed to be from a pre-Tertiary formation, that is,

[24] P. Carmody, "Trinidad as a Key to the Origin of Petroleum," a paper read before the Inst. Pet. Tech., May 10, 1921, as yet unpublished, but a résumé occurs in the *Petroleum Times*, May 21, 1921, p. 585, including analyses of oils. For Manjak see also E. H. Cunningham Craig, "San Fernando Manjak Field," Council Paper No. 3 of 1905, Trinidad, 1905.

Cretaceous sandstone, but geologists are not all agreed on this point, some suggesting that it is a pre-Cretaceous oil, others that it is a Cretaceous oil, and yet others that it is a Tertiary oil. A more recently favoured theory suggests that the oil has accumulated in its present position by downward migration from overlying Tertiaries, now removed by denudation, a theory currying favour in somewhat anomalous oil occurrences in other countries besides Trinidad. The Lower Oil group or Galeota Sand horizon produces, as at Lizard Spring, a very high-grade oil with large percentages of petrol and kerosene. The Upper Oil group (Rio Blanco Oil-sand of Cunningham Craig) is the most important producing horizon at present, and the oil is of a heavy asphaltic type with varying specific gravity; in the Point Fortin fields for example the S.G. varies from 0·907 to 0·945, while at Fyzabad it is as much as 0·977. The La Brea Oil-sand, as already stated, is essentially a horizon of migrated oil, characterized by its high specific gravity (0·950), and its sulphurous content.

A striking feature of the petroleum produced in Trinidad is the marked variation shown in composition, as evidenced by the great differences in specific gravities, percentages of petrol, kerosene, lubricating oil, sulphur, and solid residues as a result of refining; the occurrence of such a variety of oils suggests either formation originally under constantly changing conditions of deposition, or subsequent alteration in character as a result of inspissation and allied natural processes. Very probably both factors have been at work in the present instance, for we have already seen how the physical conditions altered with the growth of the Tertiary epoch, and furthermore observed cases of natural filtration are quite common in the island; in this connexion Cunningham Craig has described an interesting example at Lizard Spring, to which account the reader is referred for further information.[25] Obviously a consideration of these facts throws us back to the question of the origin of Trinidad oil, and unfortunately this still remains an unsolved problem for most people; it is not as though we were dealing with a definite oil horizon as well individualized as the Monterey Shales of Californian fields, for instance, where an associated diatomaceous fauna is indicative of the origin of the oil, thus indigenous to these rocks; in Trinidad the evidence is much more obscure, and apart from the problems of the relationship of one oil horizon to another, in themselves formidable enough to solve, so far no generally accepted theory has been propounded to explain the phenomena observed. The recent paper by Professor Carmody is mildly constructive in suggesting "Trinidad as a key to the origin of petroleum," but it lacks comprehensiveness in narrowing down the question to a vegetable origin which, while capable of explaining the occurrence of certain oil-pools in the island, is inadequate to all cases both here and in other parts of the world, as for instance in the Californian example cited above. A special plea of that author's work, however, that of close collaboration between geologist and chemist, is certainly sound, and this combination, if not initially successful in solving the local problems of Trinidad oil, may ultimately be expected to provide a solution to the question of the origin of petroleum in a broad sense, from which suitable deductions may be drawn to meet the special circumstances of cases such as the one under discussion.

It remains to mention in this economic section coals and lignites occurring in the island; these may be dismissed briefly as they are of little commercial value. The coal deposits are not extensive, and the material is of poor quality; they occur particularly at Cunapo and Montserrat, the coals of the latter locality being decidedly bituminous. Lignites, also of poor quality, occur at Chaguanas and Brasso Caparo. It is noteworthy that the above occurrences are not located in the main petroliferous region of the island.

Production of Petroleum.

One of the most characteristic features of the oil reservoirs in Trinidad is their strong tendency to exhibit lenticular disposition, particularly in the case of the upper oil horizon; these reservoirs usually consist of sand lenses intercalated with argillaceous strata, and their occurrence is determined primarily as a function of estuarine and deltaic deposition, subsequently modified by the nature and degree of deformation undergone by the enclosing strata. We have already seen that on the whole the varying phases of deposition of the Tertiary

[25] E. H. Cunningham Craig, Oil Finding, 1917, pp. 91–2.

rocks of the island are indicative of shallow water conditions, and the presence of these lenticular sand masses is clearly incompatible with deep-water sedimentation, a factor receiving support from the marked lateral variation in lithology of the deposits, previously remarked. The usual textbook diagrams of lenticular oil-pools, however, can hardly be accepted as truly illustrative of actual conditions, and the contrasted behaviour of wells often in close proximity is not so easily explainable on the assumption of the existence of several small lenses, as on this factor of lateral variation with its attendant differences of porosity of sediment. The accurate location of these structures is one of the most difficult tasks facing the geologist, and in regions of extensive folding of strata, as in Trinidad, such difficulty is doubly accentuated; it obviously implies a fundamental knowledge of the mode of origin of the sediments, their lithology, variation, and mutual relationships, supplemented by a careful study of the records of existent wells and by all the power that modern field and laboratory methods may bring to bear on the questions concerned. Then with a clear idea of the attitude of these oil-pools in depth, the subsequent location of well sites becomes a comparatively straightforward matter, and it may be safely said that the failure of many wells put down in Trinidad, as in other countries, is due largely to insufficient "ground work" in minimizing risk, quite apart from failure due to adverse circumstances over which the geologist has no control. There is a further element to be considered in this respect and that is the frequent antipathy shown by drillers to the geological staff; the gulf between them is unfortunately often a wide one, not only in some cases in Trinidad, but also in other oilfields. That it can be successfully breached by tact and collaboration of both parties is the opinion of more than one field manager known to the writer. The point is not by any means irrelevant to prosperous oil production.

Drilling is not easy in Trinidad for many reasons, chiefly owing to the rapidly changing characters of the strata, and also on account of the high gas pressure frequently met with; in many cases the sands cave badly, and this, coupled with the fact that the rocks are often dipping at fairly high angles, tends to cause delay. Water again sometimes gives trouble, and in such instances prolonged bailing has to be resorted to before production can be obtained. In areas of excessive gas pressure the buckling of casing previously lowered into the hole is of frequent occurrence; where this cannot be overcome by temporary expedient, the well has to be sealed off, and an "offset" put down at a more pertinent location. Gushers are common in some fields, and that of Apex No. 3 in November last is still fresh in the public mind; in this case a gross flow of at least 100,000 barrels of oil in eighteen hours occurred, a dam capable of holding back 50,000 barrels being washed away, the well ultimately catching fire and causing much damage. Happily, disasters on this scale are the exception rather than the rule, and usually, thanks to the ability of the drilling engineers in charge, there are comparatively few wells which come in with a "blow" that are not ultimately brought in satisfactorily, with little, if any, loss of oil.

Generally speaking, the wells are from 600 to 2,000 ft. deep, though there is no specific reason why deeper wells should not be drilled if, ceteris paribus, prospects suggest the advisability of so doing. Both standard percussion and rotary flush systems are employed, and latterly the combination of the two has been favoured, that is, starting with percussion and changing over to rotary usually at about 500 to 700 ft., though this may vary according to circumstances. As in other oilfields, however, there is no rigid rule as regards method, and each well put down is drilled according to the system best befitting the conditions obtaining in the particular area selected.

Oilfield Development.

It is not surprising, in view of the potentialities of Trinidad as an oil-producing colony, that development of its petroleum resources has been rapid, largely owing to the enterprise of British companies. The following table of the annual production of oil from 1905 gives some indication of the course of events:—

	Imp. Gallons.
1905–1909–10	368,934
1910–11	4,378,942
1911–12	9,985,748
1912–13	17,626,563
1913–14	22,523,060
1914–15	36,753,931
9 months ending Dec. 1915	23,489,362
1916	32,475,695
1917	56,080,914
1918	72,872,398
1919	64,436,632
1920	72,905,947

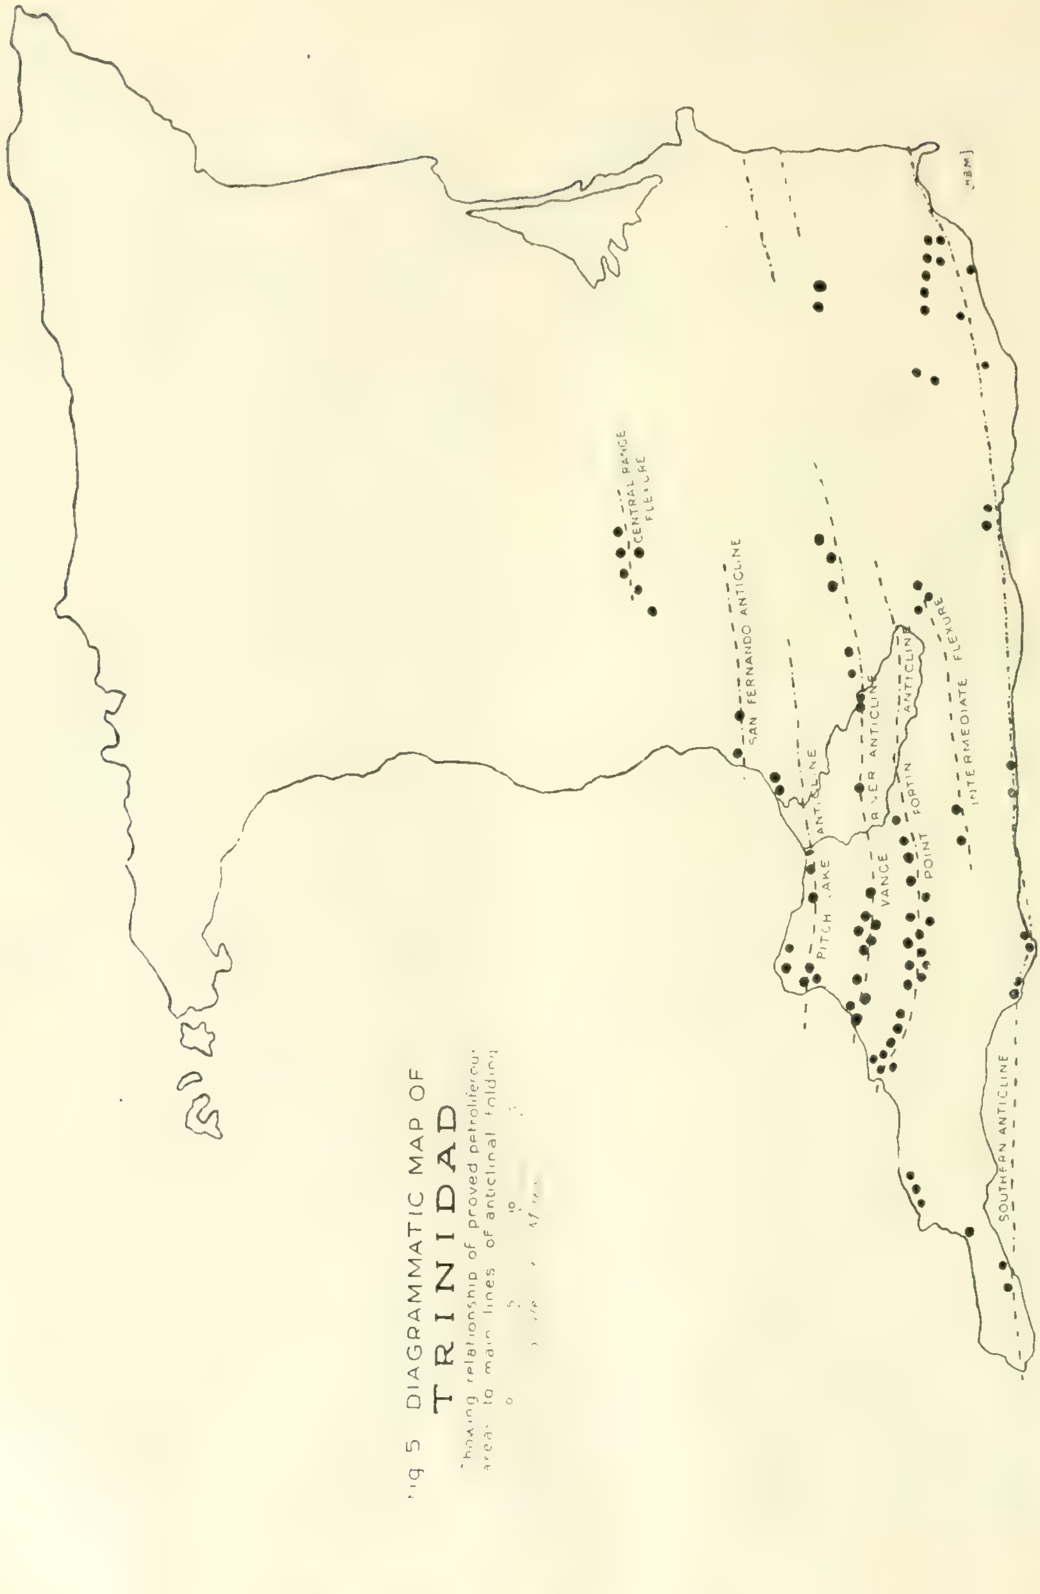

Fig 5 DIAGRAMMATIC MAP OF TRINIDAD
Showing relationship of proved petroliferous areas to main lines of anticlinal folding
0 5 10 Miles

From the above statistics it will be seen that, on the whole, the production of oil has been steadily on the increase; the dropping off in output in 1916, and again in 1919, was due to a variety of circumstances connected with the war, though in the latter case, apart from general financial depression, shortage of material, and increased costs of production prevalent, this falling off was not wholly without natural cause, a marked decline in output being noted from several of the best wells put down. While certain people were at once pessimistic enough in predicting a gradual future decrease in production thence onwards, the consensus of opinion of geologists and others best qualified to judge the trend of events in the island showed little belief in such prognostication, and the official returns for 1920 completely justify the more favourable view. We revert to the question of decreased output of oil from natural causes subsequently.

At the present time the development of the petroleum industry in Trinidad is in the hands of some thirty or more companies, some of them long established, others comparatively newcomers; by far the largest producing company is the Trinidad Leaseholds, Ltd., which has an average monthly output of some 15,000 barrels. The greatest activity from the standpoint of actual production is in the south-western portion of the island, from San Fernando to Cedros, while considerable developments are in progress in the Fort George, Piparo, Williamsville, Montserrat, and Tabaquite districts of central Trinidad. In the following description of the various oilfields it is convenient to deal with them geographically under three regions, (*a*) South-Western Peninsula, (*b*) South Coast and South-Eastern Trinidad, and (*c*) Central Trinidad.[26]

(*a*) *South-Western Peninsula.*—This includes the region to the west of a line drawn from San Fernando through Princestown to Moruga, and comprises some of the most important oilfields as yet developed in the island. In the vicinity of San Fernando itself, several interests are represented, including the Naparima Oilfields of Trinidad, Ltd., which are developing the oil resources of the Ste. Madeleine Sugar Co's. estates, comprising over 16,000 acres. To the south, the Trinidad Leaseholds, Ltd., are operating at Barrackpore, an area of 1,000 acres acquired from the Trinidad Oil and Transport Co., Ltd., in 1918; a 6 in. pipe-line has been laid connecting up with the company's main pipe-line from Forest Reserve to the shipping port at La Carrière (Point-a-Pierre). To the south of this property the Trinidad Central Oilfields, Ltd., hold prospecting rights over about 800 acres. West of the Oropuche Lagoon, the Trinidad Leaseholds, Ltd., are operating their Forest Reserve field in the Fyzabad district, with a subsidiary field at Santa Cecilia to the east; in the former field forty-six wells are now producing, and a 6 in. pipe-line exists thence through Santa Cecilia to La Carrière, a distance of 26 miles. Development of the Santa Cecilia field is in progress. In this Fyzabad district, the Apex (Trinidad) Oilfields, Ltd., have their properties, covering an area of some 800 acres; it was here that the gusher struck at well No. 3 occurred last year, to which reference has already been made; this well is now producing again. Further to the west the United British Oilfields of Trinidad, Ltd., have properties in the Guapo and La Brea districts, while the Trinidad Dominion Oil Co., besides other properties in the south-east of the island, holds some 530 acres under lease at Point Rouge. The Trinidad Central Oilfields, Ltd., also have 483 acres in the Guapo district, and other smaller companies are operating in the vicinity, which includes the Crown Lands in the Morne L'Enfer Reserve, over which the Petroleum Development Co. have prospecting rights. To the north the Pitch Lake is in the hands of the New Trinidad Lake Asphalt Co., Ltd., while the Trinidad Lake Petroleum Co., Ltd., have the oil rights on this property; there is a refinery and shipping wharf at Brighton, just west of La Brea, from which both oil and asphalt are exported. The United British Oilfields of Trinidad, Ltd., control altogether some 38,000 acres in the island, of which part is located in this peninsular region. Several properties bordering the south coast and extending eastwards towards Moruga await future development by the companies concerned.

(*b*) *South Coast and South-Eastern Trinidad.*—This region is embraced by a line drawn

[26] For reasons both of expediency and space, it is impossible to do more than mention briefly the chief companies and their properties in the Island; for further information, reference must be made to the various company reports published and to the well known "Oil and Petroleum Manual," 1921, by Walter R. Skinner.

from Moruga Point northwards through the Fort George area, thence east to Mayaro Point. The greater part of this district is undeveloped as yet, four companies having the chief interests therein. Trinidad Leaseholds, Ltd., hold under lease from the Government about 40,000 acres to the west and north of Guayaguayare Bay, just west of Galeota Point ; circumstances of war, and inadequate storage capacity and transport facilities have retarded development of this property, but considerable geological survey work has already been carried out. Trinidad Central Oilfields, Ltd., also have properties here, 974 acres at Lizard Springs and 42,216 acres at Mayaro, part held on lease and part on exploration licence ; the other two companies concerned are the United British Oilfields of Trinidad, Ltd., and the Trinidad Dominion Oil, Ltd., the latter property bordering Guayaguayare Bay and adjoining the Trinidad Leaseholds field.

(c) *Central Trinidad.*—In the central part of the island, the Trinidad Central Oilfields, Ltd., have had their enterprise rewarded by the development of the well-known field at Tabaquite, being part of a property covering some 25,730 acres, of which over 1,000 acres are held on lease ; the port of shipment is at Claxton Bay, a little to the north of Point-a-Pierre, where the company has a small refinery connected to the field at Tabaquite by a pipe-line, the distance being 18 miles. Trinidad Leaseholds, Ltd., also have oil rights over certain smaller areas in this region, as at Piparo, where developments are in progress. Following on the success achieved by the Trinidad Central Oilfields, Ltd., in this part of the island, proving the existence of valuable high-grade light oil, considerable attention is being focussed on this region, previously regarded as an unlikely area of commercial oil production. In the map (Fig. 5) the distribution of the proved petroliferous areas is shown, together with the main lines of anticlinal flexure previously described.

Conclusion.

The logical sequence to a descriptive article such as this is naturally a reference to the future oil prospects of the island, possibly almost as elusive a subject as much of its internal geology ! Many different opinions are expressed on this point, and one constantly hears the remark that "Trinidad is being overdone," at least on this side, for it is seldom made by those who have had long experience in the island. Mention has already been made of the noticeable decline in production of 1919 ; this now requires a little more detailed explanation.

The bulk of the producing wells in Trinidad have hitherto tapped the resources of the upper oil horizons, the lower in many cases lying at great depths, though not outside ultimate drilling range. This is particularly the feature of the south-western part of the island, where, although the lower sands have been proved to exist, test wells put down for the purpose of exploring the deeper oil-pools have frequently met with trouble in the shape of excessive gas pressure or strong oil-flows from overlying members of the upper oil series ; a case in point is that of a certain well put down with the intention of tapping the lower series, thought to be about 1,800 ft. below the surface, which instead struck a strong gas and oil zone at less than half this depth ; production has since been maintained from this upper horizon, and so far it has been found quite impossible to deepen the well. An instance such as this is not of isolated occurrence, and it clearly points to the persistence of as yet untapped resources nearer the surface. While there may be a tendency towards decline in production from these upper sands taking the region as a whole, one can hardly see grounds for pessimism on this account, since obviously as the upper horizons get further drained, so the gas pressure and strength of oil-flow will tend to be lessened, thus making it possible to sink deeper wells in order to tap the lower resources. And from the little we already know of these lower sands, they bid fair to be equally as important ultimately as the upper horizons have been hitherto. Further than this, there are the developments referred to in the central parts of the island, where comparatively little is known of the geological conditions ; if Tabaquite is anything to judge the future of this region by, we perceive even greater possibilities here than in the south. Add to this the potentialities of much of the undeveloped land in the south and eastern parts of the island, and it is abundantly clear that the petroleum resources of Trinidad are by no means exhausted.

Lastly, the writer may perhaps be permitted to voice the plea for greater publicity

of geological data accumulated by the geologists of the several companies concerned in oil exploration in Trinidad, and this for the benefit of both science and commerce. It is not too much to say that of no oilfield in the world of the importance of Trinidad is so little known to the general public as in this case, and it is extremely difficult to understand the traditional iron-clad secrecy prevailing among the various operative interests in this colony. Once a company has established itself on a definite property, is producing from this property, and has thus proved its economic value, what possible advantage can be served by withholding the details of the scientific evidence by which such results were achieved? We have only to study the admirable reports and technical literature extant in the United States, where every oilfield has adequate publicity in the bulletins and memoirs of the various State surveys and mining bureaus, to be regretful at the lack of similar descriptions of our own fields, and although it may be argued that no official geological survey now exists for Trinidad, that in itself is no reason for the deficiency in this case. Collaboration of the several experts professionally engaged on oil exploration and the pooling of that scientific knowledge obtained in the course of their work for both mutual and public benefit, can scarcely be detrimental to commercial interests in the long run; on the contrary, by such co-ordination future developments would tend to be carried out on a much sounder basis, that of a wider geological knowledge, and increased efficiency both in exploration and production would necessarily follow. Professor Carmody's vindication of "team work," alluded to in the introduction, may be again emphasized here, and it deserves well of those in whose hands the future of the petroleum industry of Trinidad lies.

(*Concluded.*)

Mining in Devonshire

In the Summary of Progress of the Geological Survey of Great Britain for 1920, Donald A. MacAlister gives tables of output of various minerals in Devonshire in years gone by.

Outputs of Lead, Silver, Pyrites, Arsenic, and Iron.

Lead Ore, 1845 to 1913	Tons	59,422
Lead, Metallic, extracted from above ore	Tons	38,423
Silver extracted from the above lead, 1852 to 1913	Oz.	948,291
Pyrites, Iron and Arsenical, 1853 to 1913	Tons	101,266
Arsenic, Soot and White, in addition to the Arsenical Pyrites, 1853 to 1913	Tons	98,067
Iron Oxides, 1853 to 1913	Tons	344,584

Of the lead ore produced the largest amounts came from the parishes of Beer Ferris, 25,670 tons, and Christow, 22,550 tons. The parish producing the largest amount of pyrites was Tavistock, 72,000 tons, of which 50,393 tons was arsenical. The iron oxides were partly magnetite, hematite, limonite, and shining micaceous ore. The last-named has been a feature of iron mining in Devonshire, and it has been worked from time to time at several places, being employed in the manufacture of protective paints. In the following table relating to tin and copper we give the details of output of each parish.

Outputs of Tin and Copper by Parishes.

	Tin Concentrate. Tons.	Copper Ore. Tons.	Copper derived from the Ore in previous column. Tons.
Ashburton	804	421	17
Beer Ferris	10	205	13
Belstone	1	4,036	375
Bovey Tracey	—	2,300	86
Buckfastleigh	—	29,680	1,965

Totals	6,066	1,096,968	71,737

MINING MODELS AT SOUTH KENSINGTON

This article contains an account of models explanatory of mining operations, designed and made by Mr. G. W. Leech, M.Inst.M.M., and recently added to the Science Museum, South Kensington.

The Science Museum at South Kensington is not so well known as it should be, nor does it receive the support from the Government that teachers and students would desire. The collection of plant, models, etc., relating to mining shows considerable unevenness, and there are breaks in the historical connexion. This condition is caused by variations in the interest taken by those in charge. Fortunately for the mining profession, the director of the Museum from 1911 to 1918, Sir Francis G. Ogilvy, was much interested in these subjects, and his services in helping the Royal School of Mines as well as the Science Museum are well known. During his regime a great many new models and apparatus were added, so that the collection and also the new catalogue are now of much heightened value. During the years 1915 to 1917 and 1918 to 1920 Mr. G. W. Leech, M.Inst.M.M., was engaged in designing and building models illustrating mining methods. Altogether about forty of these models have been added to the collection, and we take this opportunity of thanking Sir Francis and Mr. Leech, on behalf of the mining profession, for the excellent services they have rendered in the cause of technical education.

To give readers an idea of the nature of the new work, we reproduce in this article descriptions of five models, together with photographs, the descriptions being taken from the official guide-book to the collection. It will be seen that this guide-book constitutes quite a useful exposition of modern methods of mining.

(1) *Flat-Back Stoping, Overhand System.*—In this method of stoping the ore is broken out in a series of slices of more or less regular shape extending the whole length and width of the vein between the winzes and walls, keeping the back (roof) as uniform and level as the nature of the ore will permit. The model represents a contact ore deposit between a granite foot-wall and a schist hanging wall (that is, a good foot-wall but a weak hanging wall); the ore is supposed to stand well. As the ore is removed it is necessary to fill the stopes with waste rock; this filling is distributed by a light car on a portable track, and is carried up to within 5 to 8 ft. of the roof. Ore chutes or passes are built up by cross-logging through

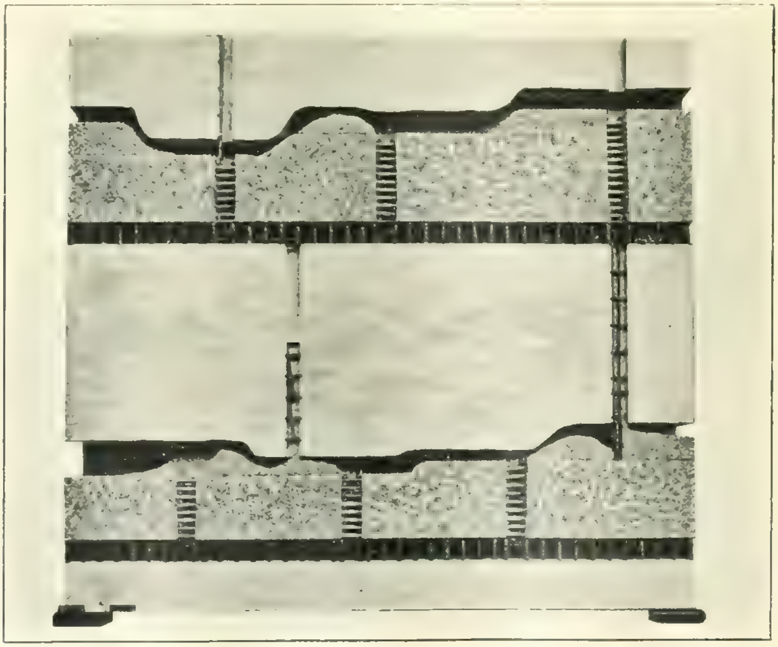

Fig. 1.—Flat Back Stoping.

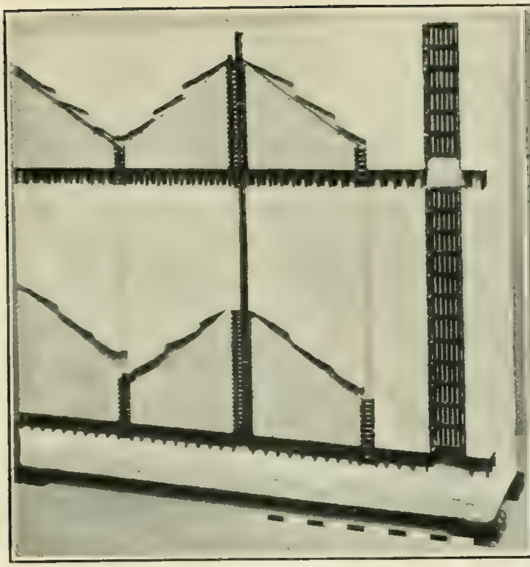

FIG. 2.—RILL STOPING.

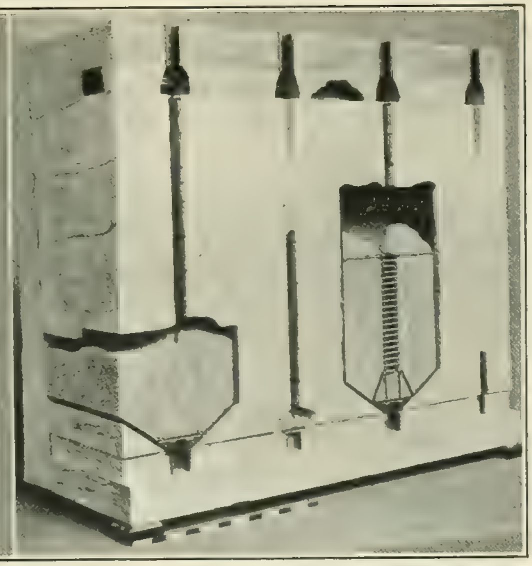

FIG. 3.—GILMAN CUT-AND-FILL SYSTEM.

the waste filling. When waste rock is cheap the method is economical, not more than 5% of the ore being left in the mine. Prospecting work can be carried out from the stopes by means of cross-cuts, etc., and other development work can be carried out more conveniently than from a rill or shrinkage stope. Another advantage of the system is that the rich ore can be sorted out and the ore too poor to pay for treatment can be left behind. The disadvantage of the method, particularly in large stopes, is the cost of transport of the ore to the passes, owing to the shovelling and trucking involved. In some cases this is reduced by the use of wheelbarrows. A corresponding drawback occurs when the stope is being filled, as much shovelling is necessary to distribute the waste rock.

(2) *Rill Stoping.*—This sectional model represents the rill method of stoping-out ore from a vein, a method that is often employed in veins of narrow to medium width, and where filling is needed to support the walls. The name is given to it because the ore gravitates or " rills " in the ore-passes or chutes. Under favourable conditions the ore-body is divided into blocks by levels about 100 ft. apart, and by winzes 50 to 60 ft. distant from one another, but these dimensions will vary according to the character of the deposit. In the model, a section of a portion only of the mine is shown, comprising one of the waste shafts connected with the surface for filling the stoped-out ground. The stopes are worked at angles with the horizontal between 35° and 45°. The flatter angle is that shown in the model. At the steeper angle, should the width of the vein increase, the miner has to exercise considerable caution in moving from the working face. After a slice of ore from 10 to 15 ft. in height has been worked out and taken away, waste rock filling is let down the winze, and if the ore is of high grade, a mat of boards, as shown, is laid on the waste filling to receive the next slice of ore. In the lower stopes the ore is supposed to be of low grade and no timber mat is used. This stope is in the process of being filled with waste rock.

(3) *Gilman Cut-and-Fill System.*—This model shows a method of mining used extensively in Arizona, and, with various adaptations, in stoping the large sulphide ore-bodies found in this and other mining districts of the United States. The method is said to have been named after an American engineer who introduced it. The system consists in blocking out the ore in sections of 40 to 50 ft., with cross-cuts driven from the main drive to the limits of the ore-body on the hanging and foot-wall sides. A section of the stope on the foot-wall side of the drive is represented. Vertical rises are driven upwards from the cross-cuts connected with winzes sunk from the upper level ; later these provide a means of filling the stope with waste rock and serve

for ore chutes and passes. These cross-cuts are the first step in stoping, and the next step consists in widening the ground a little at the side of the cross-cut to permit the temporary timbers to be placed in position. Flooring is laid so as to allow the ore to fall, by removing the short planks, into the trucks below. When sufficient ground has been broken out these temporary sets are replaced by regular timber sets of posts, inclined caps, and vertical sills, with planks to form a mat between the gob of waste rock and the ore below and along either side. After each successive ore-cut from 10 to 12 ft. above the floor, the ore is drawn off, the floors taken up, and the waste rock run in to the desired height. The floor is then relaid to receive the next cut. In the earlier stages of stoping all the ore is not removed as soon as broken down, but is allowed to accumulate as a floor for the miner to stand on. The work at successive stages, numbered 1, 2, 3, and 4, and the method of timbering the workings are shown in the model.

(4) *Top Slicing.*—This sectional model represents a method of extraction used principally in mining large soft ore-bodies. The system is a modification of the long-wall retreating method worked under an artificial roof of timber called a mat. The top of the ore-body is removed either by open stoping or sub-level caving, and a double floor of plank 2 in. thick is laid down. The overburden is then caved-in on top of the mat. A car level is laid out at about 50 ft. below the mat, and the ore is divided by drifts, winzes, and rises into blocks 30 to 40 ft. wide. Commencing at the boundary or walls of the ore, slices 11 ft. in height by 30 to 40 ft. wide are mined beneath the mat, which is supported meanwhile by posts and round unframed caps. As the slicing advances, the timber mat is caved by blasting the posts behind the working face. This method allows a larger and more regular output from the working faces than if square-set timbering is used, but, owing to the rough floor and other conditions, the breaking and shovelling of the ore is not done so economically; the amount of timber used, however, as compared with square sets, is small.

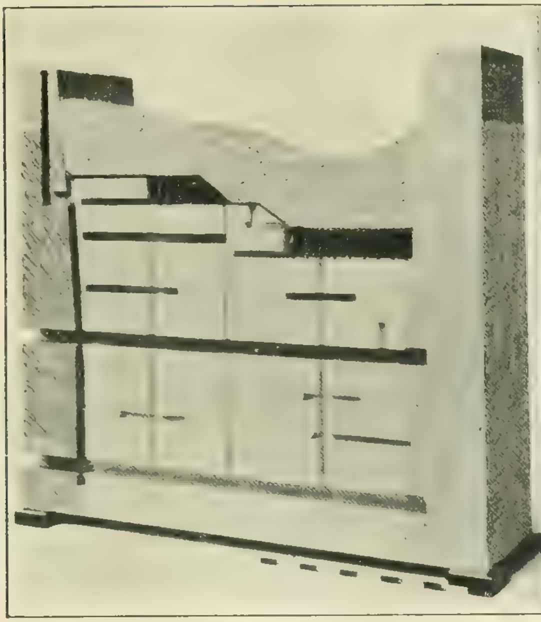
(5) *Ore in Sight.*—This model represents the blocking out of ore in a mine, and illustrates some of the difficulties met with in estimating the quantity of ore in situ. One of the purposes of blocking out the ore in a mine by drifts, winzes, and rises—in addition to the primary one of the work of extraction—is to expose the boundaries of the ore deposit in three dimensions for the purpose of estimating quantities and values contained in the deposit. Owing to the irregular way in which ore deposits occur, such estimates may vary considerably. The Institution of Mining and Metallurgy, recognizing the importance to the mining industry and to the public generally of defining the terms "Ore in Sight," appointed a committee to consider what steps might be taken in the matter. After report and consideration, the Institution made the following recommendations:—

(1) That members of the Institution should not make use of the term "Ore in Sight" in their reports without indicating in the most explicit manner the data upon which the estimate is based; and that it is most desirable that estimates should be illustrated by drawings.

(2) That as the term "Ore in Sight" is frequently used to indicate two separate factors in an estimate, namely: (*a*) Ore blocked out, that is, ore exposed on at least three sides within reasonable distance of each other; and (*b*) ore which may be reasonably assumed to exist though not actually blocked out; these two factors should in all cases be kept distinct, as (*a*) is governed by fixed rules, while (*b*) is dependent upon individual judgment and local experience.

(3) That in making use of the term "Ore in Sight" an engineer should demonstrate that the ore so denominated is capable of being profitably extracted under the working conditions obtaining in the district.

The model illustrates these recommendations. At B B the ore is blocked out on four sides into 50 ft. blocks. At C the ore is blocked out on three sides, but as the top drift is partly in barren ground, owing to the lode not outcropping to the surface, the difficulty of estimation is increased. At D the ore is blocked out on four sides into 100 ft. blocks; at L and T indications of intrusions of barren rock of unknown extent occur. In the case represented, on extraction of the ore, the barren mass was found to be of the shape shown by the dotted line. At E the ore is blocked out on three sides, but no winze has been sunk at Z; the character of the ore at this point, however, may reasonably be assumed from the data supplied by the drifts above and below. The same remark



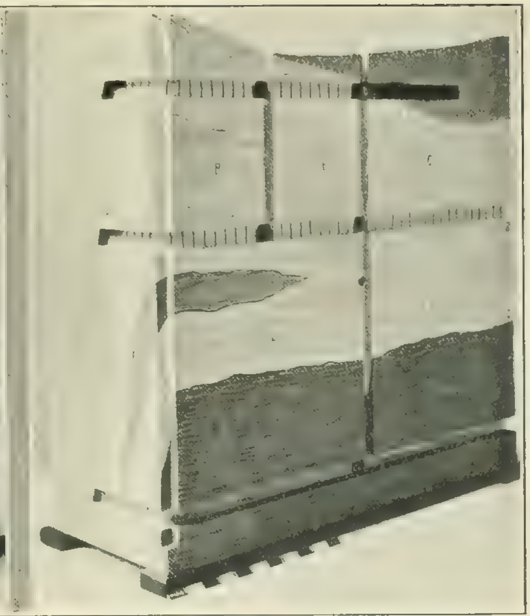


FIG. 4. TOP SLICING.

FIG. 5.—ORE IN SIGHT.

applies to G G. Blue lines on the model every 5 to 10 ft. indicate the points where samples for assaying are taken.

As we have already mentioned, the models described in the foregoing paragraphs are only five out of over thirty made by Mr. Leech. To give an idea of the full scope of his work, we give herewith a list of titles of the others, at the same time expressing regret that space prevents us giving the descriptions and illustrations: Shrinkage stoping; sub-level caving system; milling system of mining; block slicing; mine head frame; prospector's shaft; Australian spaced-box mine shaft; Rand shaft timbering; main adit or level timbering; four-piece level set timbering; four-piece level set for side pressure; stull timbering; angle setting; stull timbering with varying angles of walls; three-piece stull timbering; stull and false stull; stull and saddleback timbering; saddleback stulls with ore chute; reinforced stulls; Chinaman ore chute; timbering level sets with stoping beneath; square-set timbering for stopes on Eureka system; square-set timbering for stopes on Bingham system; square-set timbering for stopes on Burlingame system; square-set timbering with round timber; rock-drill staging; end tipping truck; all-round tipping truck; froth flotation plant; magnetic separator; cyanide plant; etc., etc.

The Institute of Metals

The autumn meeting of the Institute of Metals was held at Birmingham on September 21 and 22. The following papers were read and discussed: The Properties of some Nickel-Aluminium-Copper Alloys, by A. A. Read and R. H. Greaves; The Effect of Increasing Proportions of Lead in the Properties of Admiralty Gun-metal, by R. T. Rolfe; The Casting of Brass Ingots, by R. Genders; The Density of the Zinc-Copper Alloys, by T. G. Bamford; Experiments in the Working and Annealing of Copper, by Dr. F. Johnson; The Effects of Progressive Cold Drawing upon some of the Physical Properties of Low-Tin Bronze, by W. E. Atkins and W. Cartwright; The Extrusion Defect, by R. Genders; The Use of the Scleroscope on Light Specimens of Metals, by F. S. Tritton; The Annealing of Rolled Zinc, by D. H. Ingall; The Constitution and Age-Hardening of the Alloys of Aluminium with Magnesium and Silicon, by D. Hanson and M. L. V. Gayler; The Electrolytic Etching of Metals, by F. Adcock; Electron, the High-Magnesium Alloy, by S. Beckingsale. A number of visits were paid to metallurgical works in the neighbourhood, and there was also an interesting visit to the Birmingham University, where the courses of instruction were intimately studied.

THE CHARACTERISTICS OF CASSITERITE

By E. H. DAVISON, B.Sc., F.G.S.

Many minerals are easily mistaken for cassiterite. The author gives a concise statement dealing with this subject, intended for the guidance of workers in the field.

Cassiterite is a mineral which, owing to its variation in colour and texture, is by no means easy to recognize with certainty. It has, to the writer's knowledge, happened that such minerals as blende, axinite, and zircon, have been mistaken for it by observers with considerable experience. Though its characters are given in detail in Dana's *System of Mineralogy*, and more or less completely in other textbooks (especially well in Collins' *Mineralogy of Cornwall and Devon*), it is felt that the following summary of its physical and optical characters and its chief characteristic chemical reactions may be of use to those who have to deal with tin ores and alluvials. Special reference is made in connexion with other minerals often mistaken for it.

Physical Characteristics.—Cassiterite has a hardness of from 6 to 7 on Mohs' scale; it therefore cannot be scratched by a knife. Its specific gravity varies from 6·8 to 7·1. It has imperfect cleavage, which is often not to be observed, with uneven or subconchoidal fracture, brittle character, and adamantine lustre. Its streak is white to pale buff, and it may be nearly transparent or opaque.

The colour varies from black through brown, red, and yellow, to pale buff or white. The powdered mineral is of a pale buff colour, unless coloured by admixture with iron oxide.

The following varieties are recognized :—

Crystalline cassiterite, "diamond tin," in fair-sized tetragonal crystals in low pyramids or short prisms.

"Sparable tin," in small acute almost acicular tetragonal crystals.

"Rosin tin," reddish or yellowish in colour and translucent.

"Ruby tin," ruby red and nearly transparent.

"Wood tin," brown to buff in colour with a concentric fibrous structure.

"Toad's eye tin," a variety of cassiterite occurring in small spherical masses, with radiating texture, embedded in massive cassiterite of a darker or paler tint.

"Stream tin," in more or less rounded grains or pebbles.

"Black tin" is the miner's term used to indicate tin as tin oxide in whatever form it occurs.

Optical Characteristics.—It is often useful to examine a sample under the microscope in the form of fine powder or as a constituent of a micro-section of a rock or veinstone. When this method is used several minerals are likely to be confused with cassiterite which would be readily detected in the hand specimen.

Colour in transmitted light varies from deep red-brown through pale brown or yellow to colourless.

Cleavage (only occasionally seen) parallel.

Refractive index 1·99 to 2·09, very high relief.

Zoning common and well shown.

Pleochroism none or very feeble.

Polarization colours very high, simple twins common.

Colour in reflected light pale buff or white.

"Wood tin" shows concentric radiating fibres which give a black cross between crossed nicols.

"Wood tin" is seen under the microscope to consist of concentrically arranged crystalline prisms which give the usual birefringence colours between crossed nicols and is in no sense noncrystalline, each individual prism being readily distinguished.

"Toad's eye tin" consists in come cases of quartz crystals zoned by included granules of cassiterite, which are often of extremely minute size.

The characteristic buff colour of cassiterite in reflected light is one of the most distinctive characters under the microscope and of great help in distinguishing cassiterite from minerals with characters otherwise similar.

Blowpipe Reactions.—Heated on charcoal gives a white incrustation which turns blue or blue-green on moistening with cobalt nitrate and reheating. Fused on, charcoal with soda yields a bead of metallic tin as well as incrustation. Potassium cyanide may be used instead of "soda" with advantage.

Chemical Test.—When cassiterite is placed in contact with zinc and hydrochloric acid it

TABLE SHOWING CHARACTERS OF CASSITERITE AND OF MINERALS LIKELY TO BE MISTAKEN FOR IT.

Mineral.	*Sp.Gr.*	*Hardness.*	*Crystal Form.*	*Blowpipe and Chemical Tests.*	*Optical Characters.*
Cassiterite. SnO_2.	6·8–7·1	6–7	Tetragonal pyramids or prisms.	Metallic bead with soda or potass. cyanide on charcoal. Incrustration on charcoal which gives blue-green with cobalt nitrate.	Pleochroism feeble or none. Birefringence very high. Buff or white in reflected light.
Zinc Blende. ZnS.	4·0	3·5	Cubic often in tetrahedrons.	Incrustation on charcoal which gives grass green with cobalt nitrate.	Isotropic. Buff or grey in reflected light.
Ilmenite. $FeOTiO_2$.	4·7	5·5	Tabular trigonal.	Yellow solution with potass. bisulphate turns violet when reduced by tin.	Opaque in transmitted light. Black usually with buff patches of leucoxene in reflected light.
Wolfram. $(FeMn)WO_4$	7·5	5·5	Tabular crystals monoclinic.	Microcosmic bead is deep red. Decomposed by HCl, the solution giving a blue colour when reduced by zinc. Streak, red brown.	Black, or dark red if very thin. Parallel cleavage. Lath-shaped sections.
Rutile. TiO_2.	4·2	6·5	Crystals like cassiterite, often geniculate twins.	Microcosmic bead violet in reducing flame. Fused with potass. bisulphate gives a solution which yields violet colour when reduced by tin.	Brown, red, yellow, or grey. Refractive index 2·9. Birefringence very high. Slightly pleochroic.
Zircon. ZrO_2SiO_2.	4·7	7·5	Prisms with pyramid caps tetragonal.	On heating in bunsen flame brown varieties change to red and smoky varieties to pale green or colourless.	Pleochroism none. Birefringence very high. Black in reflected light.
Tourmaline, Borosilicate of Al, etc.	3·1	7·5	Prisms with pyramid top trigonal.	Gives a transient green flame when heated on Pt. wire with potass. bisulphate, and fluor.	Strongly pleochroic. Maximum absorption when vertical. Birefringence very high.
Garnet. $3R''O,R_2'''O_3,3SiO_2$.	3·7–4	7·5	Dodecahedra. Cubic.	———	Isotropic.
Axinite. Borosilicate of Ca, etc.	3·3	6·5	Flat crystals triclinic.	Intumesces in blowpipe flame.	Strongly pleochroic. Birefringence weak.

becomes coated with a film of metallic tin, and this serves as a very useful test for the mineral, especially in testing alluvial gravels. Place the specimen in a zinc dish and pour on dilute hydrochloric acid. After a few minutes' action remove and wash the specimen. The cassiterite grains or crystals will be coated with grey metallic tin. This reaction gives good results with all varieties of cassiterite, except "wood tin," which requires extra long treatment and must be crushed to a coarse sand.

Minerals likely to be mistaken for Cassiterite.—In the veinstone cassiterite is most likely to be confused with tourmaline, zinc-blende, wolfram, and garnet; in the alluvial gravel with zircon, ilmenite, garnet, rutile, and tourmaline; and under the microscope with tourmaline and zircon.

The table above gives the characteristics of each of these minerals so that they may be readily compared and identified. By use of this table it should be possible to differentiate between the various minerals which on first sight may be taken for cassiterite, and confusion between this mineral and ilmenite and garnet, for instance, should be avoided.

THE GYRO COMPASS FOR SURVEYORS

In the August issue British Patent 18,346 of 1920 was quoted, giving particulars of the gyroscopic compass for surveyors made by Anschütz & Co., of Kiel. Since then the following descriptive article has been sent us by this firm.

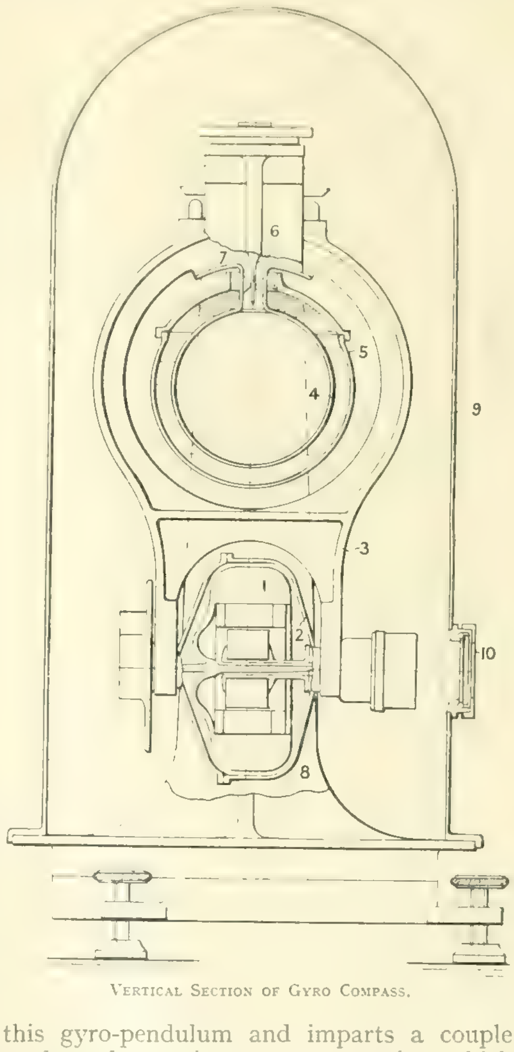
It is known to every mining engineer that the needle underground, especially in rock containing ore, is exposed to so many and complicated disturbances that it becomes almost impossible to get even an approximate indication of the magnetic meridian. The difficulty is so much the greater as there is no means of checking a deviation underground, which above ground can be done by comparing the reading of the compass with the meridian line found by taking terrestrical or or astronomical bearings.

For navigation the unreliable magnetic compass has already given place to a perfect substitute in the non-magnetic gyro compass. This apparatus is an invention of Dr. Anschütz-Kaempfe, of Munich. After more than ten years of persevering investigations and experiments he succeeded in 1908 in designing an apparatus fit for use on board ship, and brought it soon to a high degree of perfection. Others have since appeared on the market employing the same principle.

The design of the gyro compass is founded exclusively on dynamical laws, and the instrument is free from all deficiencies of the magnetic compass without introducing others in their place.

It was desirable to employ this new indicator of direction also for tunnelling and mining purposes, as there really was a great need for a non-magnetic compass in this branch of industry. This idea has long been followed by Anschütz & Co., of Kiel-Neumühlen, and it is due to the technical head of this firm, Dr. Max Schuler, that the investigations in this line were finally crowned by success. A surveying gyro compass has been designed showing true north with such exactness that it fully satisfies the demands of the surveying engineer. The apparatus as built indicates the meridian with an exactness of a half-minute of arc. This exactness may perhaps even be surpassed in future.

Those who are not well acquainted with the latest nautical developments will appreciate a short explanation of the principle of the new compass. In the gyro compass the needle is replaced by a rapidly rotating gyrostat as directive element. This gyrostat spins about a horizontal axis and is suspended in such a manner that the metacentre lies a small distance below the point of suspension. Gravity keeps the axle of such gyrostat horizontal. The earth's rotation acts upon



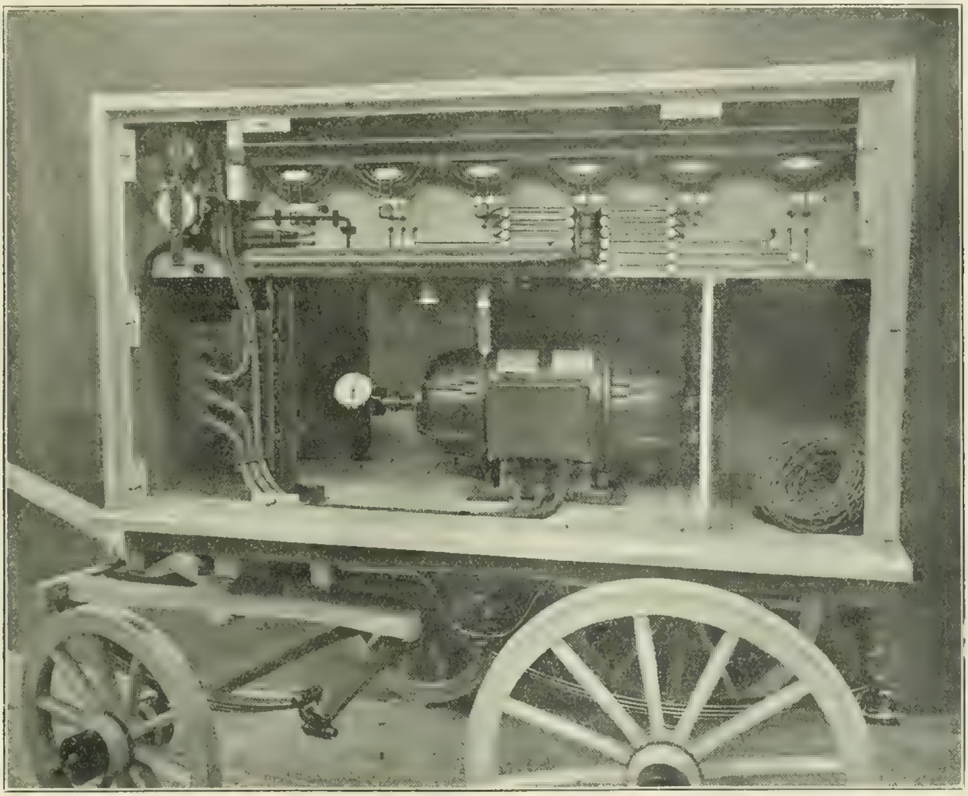
Vertical Section of Gyro Compass.

this gyro-pendulum and imparts a couple to the axle, causing a gyro-precession, which continues until the axle stands in the plane of the meridian.

The suspension of the gyrostat in the Anschütz compass is practically frictionless, being attached to a globular float immersed in a mercury bath. As there is no friction to

reduce the oscillations of the axle while settling into the meridian plane, it does not come to rest, but continues to swing to and fro about the meridian with very slowly decreasing amplitudes. In the case of the gyro compass for navigation it is necessary to fit the gyro system with a damping device to reduce these oscillations. The surveying compass does not require such attachment, as it would only diminish its exactness, and there is no difficulty in reading the true casing can be raised in such a manner that the floating system is fixed rigidly to the supporting bracket (*8*), whereby the upper opening of the mercury cup is closed, and no mercury can spill out of it during the transport.

The fly-wheel with the axle is turned out of one piece of high-class chrome-nickel steel. This is necessary because of the enormous centrifugal force developed, as the gyro spins at a speed of 20,000 revolutions per minute.



Transformer for Generating Current for Gyro Compass.

meridian by taking the average of a few oscillations.

The vertical section indicates the construction of the instrument. The fly-wheel (*1*) is pivoted horizontally in the gyro-casing (*2*), which by a bracket (*3*), is rigidly attached to the hollow globular steel float (*4*) immersed in mercury contained in the mercury cup (*5*). By a centre-pin (*6*), playing in a sharp-edged neck-ring (*7*), the floating system is kept in the middle of the suspension, supported by a bracket (*8*).

In order to make the instrument readily portable the bracket (*3*) with float and gyro- The axle is designed according to the Laval principle, and is pivoted in high-precision ball-bearings, which are lubricated by oil wicks. The gyrostat is designed as a three-phase motor with short-circuited rotor. The rotor is fixed in the bell-shaped fly-wheel. The stator is fixed to the gyro-casing, and encloses the gyro-axle. It is enclosed by the rotor, with very little space between them. The fly-wheel is at the same time the ring of the rotor, which, otherwise, could not resist the enormous centrifugal forces.

The three-phase current driving the gyrostat is generated by a transformer from con-

tinuous to three-phase. The exactness of indication requires a perfectly constant periodicity of the 333-cycle three-phase current; the generator, therefore, must be designed and constructed with special care. For use in mining and tunnelling the generator can be fitted on a cart as shown, which also carries the switches, regulators, fuses, and electric measuring instruments. This carriage can remain in the main gallery, while the compass, connected to it by a cable, is used in a narrow side-gallery.

The three phases of the current are conducted without friction to the gyrostat. Phase 1 passes through centre-pin (*6*) dipping into a few drops of mercury contained in a steel vessel below neck-ring (*7*). Phase 2 goes in the same way through a contact-pin and a second contact-vessel, not shown on the drawing. Phase 3 is in short-circuit with the mercury-cup (*5*) and passes through the mercury to the float (*4*), where it is taken up by an insulated wire.

The whole gyro compass is contained in an air-tight binnacle (*9*) filled with hydrogen. In this way the compass is protected against all disturbances by incompetent or incautious handling, the friction is reduced to a minimum, the consumption of current is considerably diminished, and the rotating parts last longer. The oil greasing the ball-bearings cannot get thick, which, of course, is of great advantage to the security of working. The mercury in the contact-vessels cannot oxidize, because of the complete absence of oxygen. Moreover, dirt and vapour cannot enter the binnacle, which is of importance, as they could become fatal to the inner parts of the apparatus worked with such mathematical precision, especially because in an air-binnacle it would be necessary to cool the gyro by a continuous draught.

The reading of the indication is done through a window (*10*) in the gas-binnacle. For this purpose a mirror reading of the Poggendorf type is employed. The curve of oscillation is traced on millimetre-paper. The average of these oscillations gives a reading of the true meridian with an exactness of half a minute of arc. The mirror is fixed to the gyro-casing in front of the inspection window (*10*). The gyro-casing with mirror can be turned about the axis of the gyro, that is, the centre of the mirror. Without turning the mirror 180° at every reading it would be impossible to test the proper position, if it is desired to keep the errors within the limits of one minute of arc or less. The securing of the mirror to the gyro-casing presents the advantage that any changes of shape of the supporting bracket (*3*) and of the float (*4*) do not affect the reading. This disposition also makes it permissible to leave a little more space between the centre-pin and neck-ring, with the result of reducing friction about the vertical axis.

LETTERS TO THE EDITOR

The Origin of Primary Ore Deposits

The Editor:

SIR—Dr. Morrow Campbell's letter in the September number of the MAGAZINE needs a few observations from me, if you will kindly grant me a little space.

Dr. Campbell says he made no attempt at explaining the well-known features of the different classes of ore-bodies. From the title of his paper alone I submit that most readers would conclude that was the intention. I do not see how the inquiries referred to in the second paragraph of his letter can explain the origin of primary ore deposits if they cannot explain the various forms in which such bodies occur. It is largely in that way that the sufficiency of an idea or a combination of ideas regarding genesis can be tested. Any number of suggestions may be made in the laboratory, but it is only such as fit the facts observed in the mine that can be accepted. It is because Dr. Campbell's suggestions will not explain those facts as put forward in the May number of the MAGAZINE that I say they fail.

As Dr. Campbell has not before him the work of Carl Barus on "Igneous Fusion and Ebullition" (United States Geographical Survey Bulletin 103), I may perhaps be allowed to introduce here a few remarks from that author. On p. 41 he says: "I also made special experiments on the floating of solid rocks on the molten magma. To my surprise, such flotation always occurs, notwithstanding the fact that originally the cold rock must be 10% more dense than the molten rock. It soon appeared, however, that the cause of such flotation is crudely mechanical, since the rock, in virtue of its weight, simultaneously hollows out a cavity and chills it, thus forming a little solid boat on which it floats on the viscous slag below." I think the viscosity of the magma combined

with the reduced density of the newly formed solid are sufficient to account for the flotation of the latter. Barus shows that the molten magma was sufficiently sticky to be drawn out in threads when the temperature of the magma was 250° C. higher than that at which it became solid.

In paragraph 3 of his letter Dr. Campbell says: "That an aqueous mother-liquor is given off by magmas, which, on consolidation, yield granite, is so widely accepted that it seems unreasonable to regard it as anything but a fact." Wide acceptance of ideas does not prove them to be true, or many of the so-called explanations in geology, now discredited, would be still in full favour.

In paragraph 8 Dr. Campbell says: "Mr. Kendall asserts that the basic rocks do not contain free bases with which the free silica in granite could have combined originally." My statement with reference to this matter was the following: "The same sort of argument leads to the conclusion that the basic rocks did not come from a substance having the mineral constitution of diorite. If the free silica of granite was previously combined, what has become of the bases with which it was united. They are not found in the more basic rocks." This is a very different statement from that attributed to me by Dr. Campbell. Later, in this connexion, Dr. Campbell says: "If Mr. Kendall realizes that the bases in calcium carbonate and sodium chloride, as well as magnetite, were originally combined with silica, he will probably admit that the conclusion he has arrived at on this subject is not at all a safe one." I do realize that the bases of the first two of these substances were originally combined with silica, but I also realize that their separation from that mineral was not effected until long after the differentiation and consolidation of the magma from which the silicates originated. That subsequent to the formation of the various plutonic rocks, and their appearance at the earth's surface, the felspars, amphiboles, and pyroxenes—largely composing those rocks—were subjected to decomposition and severe denudation. It was then that the calcium and sodium Dr. Campbell refers to were liberated, as well as the substances forming the argillaceous and siliceous rocks, which form such a large part of the earth's crust. But neither the salt in the oceans, nor the lime in the calcareous rocks have anything to do with the appearance of free silica in the granite.

I need not further remark on the difference between Dr. Campbell's definition of a primary ore and that suggested by me, beyond saying that Dr. Campbell bases on a highly disputable hypothesis, while I follow the results of visual and other direct observations.

Dr. Campbell's remarks about the Leadville ores are too general to deal with, but it may be stated that there are both primary and secondary ores in those mines. It would be interesting if Dr. Campbell would describe in detail the most important of the "many galena and other sulphide ores that he regards as not primary but secondary," and explain how they were derived from primary ores.

J. D. Kendall.

London, *September* 23.

The Real Value of Gold

The Editor:

Sir—I read with interest Mr. Speak's article on this all-important question. He approaches and discusses the question of the real value of gold partly from the point of view of the gold-producer and partly from what we may call the view of the wire-puller. I am desirous of making some observations on this subject from the point of view of the relation of the productive effort of human beings, as expressed in goods, commodities, and things, to the purchasing value of currency.

Firstly, the real value of gold is what we human beings make it, either considered in the sense of it being a commodity or in the sense of its function as currency; this self-evident fact I expect all admit.

Secondly, gold is, for the purposes of currency, given a standard or fixed value, which, among other things, enables variations in the efficiency methods and productive effort of us human beings, considered either collectively or individually, to be noted, regulated, and controlled.

For instance, making gold some fixed standard value, and issuing currency tokens based on this fixed value, serves the same purpose in one sphere of human activity in exchange of goods, commodities, things, and services as does the fixing of a standard lb. weight for measuring quantities or a standard foot for measuring lengths or distances.

Mr. Speak suggests that the value of gold should be increased approximately 50%, as the best solution for overcoming our present troubles and the general state of

depression and unrest now existing. It seems to me he overlooks several important factors and their real significance and influence on controlling and regulating the actual purchasing value of currency either in goods and commodities or in determining the amount that can be paid for services rendered in the performance of particular classes of work.

What is implied in this statement will be better understood from an appreciation of the remarks that follow.

If the real value, or a new standard value for gold, is fixed at, say, 50% above the pre-war gold standard, the resultant effect will be that the amount of gold that is supposed to represent the value of a one-pound currency note will be 50% less than before. The purchasing value of a pound note will fall just by this amount, simply because its purchasing value is ultimately determined by the goods, commodities, and things we human beings are able to obtain in exchange for the pound sterling.

Human beings determine the exchange value of commodities, not money, in actual fact.

Money or currency, after all, if we work right back to first causes, is only the lubricant whereby human effort and human activity is scientifically directed to produce goods, commodities, and things at maximum capacity with least inconvenience, so that the individual secures the results of his effort in producing goods and in services rendered in the easiest and most convenient way.

Next, if the standard value of gold is increased 50% artificially by a Government decree, through pressure brought to bear by wire-pullers, then what will happen will be that American wheat will advance in price in terms of our currency 50%. Our quartern loaf of bread, instead of costing us as now 1s., would cost 1s. 6d. ; an ounce of tobacco would cost not 1s. as now, but 1s. 6d. ; meat and everything else would go up in proportion ; and the only remedy for us would be to raise wages of workmen 50% in harmony, and likewise salaries and emoluments of all other workers. In other words the ball of inflation would be set rolling full force all over again.

Does Mr. Speak really believe the copper producer will be content to sell his copper for, say, £70 per ton as at present when the standard value of gold is increased in price 50%, and the fractional part of an ounce of gold that is taken to represent a pound sterling is reduced by 50% ?

The producer will probably agree to exchange the same amount of copper for the same equivalent amount of gold as at present, but not for the same equivalent number of currency notes as at present ; that is where the rub comes in ! Producers of all other commodities would do exactly the same. If this much is not conceded, then why not change the standard lb. weight and call the new standard lb. that weight which is represented by 1½ lb. to-day ?

Of course, everyone knows what the resultant effect would be if this were done. It would first of all create chaotic conditions, and secondly it would make absolutely no difference to the actual quantity of wheat, meat, tobacco, or anything else, we could obtain from producers in exchange for currency. That is, it would not improve the purchasing value of currency. What would apply if the standard lb. weight were altered would apply equally if the amount of gold that represents a pound note were altered.

No, it is the law of supply and demand that is at work and in operation which is causing prices for goods and commodities and wages paid for services to gradually fall and tumble, or, in other words, deflation is being forced upon us as a nation, because other nations are producing the same goods and commodities we produce and export at less cost and paying lower wages for services than we are.

In order to compete and retain our foreign trade and markets we are being forced to scale down our prices.

If England is to meet the new conditions that confront her we as a nation of people must : (1) Reduce the burdens of taxation falling on the people and on industry, that is, State expenditure and extravagance should be curtailed ; (2) improve our efficiency methods in all spheres of human activity ; (3) Increase the amount of our productive effort while at work. The coal miner should strive to increase the output of coal per month per man employed, and the same applies to the working man in all other trades and industries.

If all three of the above factors are made to work in harmony, then the purchasing value of a pound sterling will increase, and a state of prosperity return to trade and the people of England.

It seems to me to be the duty of our Government to adopt every legitimate means in their power to try and bring about deflation, because the real cause of our trade

slump and the depression that exists in the country is due to external pressure ; that is, other nations are encroaching on, and entering our markets at home and abroad, underselling and outbidding us as traders.

The index whereby we are able to judge of the actual position of affairs is by noting what the purchasing value of our pound sterling is now, compared with its purchasing value in pre-war days.

What real difference will it make to a producer of goods if, say, to-day he produces 10,000 things for £1,000, and owing to falling prices he is only able to realize £800 on them, if he is still able to produce a like number of the same things to-morrow for the £800 received for the others ?

Again, if £500 will purchase in five years time what £1,000 purchases to-day, what difference does it make to any person then if they only receive £500 in exchange for their £1,000 ? The purchasing value of both are equal, everyone loses nothing in reality, the only difference being that £1 in five years would go as far in purchasing goods, commodities, and services as £2 to-day.

This, then, gives another side of the picture approached from a different point of view on the subject of the real value of gold, and rather points to the fact that deflation would if carried to its logical practical conclusion establish a stable currency which would enable the trade and commerce of the country to revive rapidly.

Gold considered as a commodity is not discussed here, as it would make this reply too long, but stated shortly, fluctuating exchange rates between nations, due to fluctuating trade balances, automatically determine the real value of gold as a commodity ; or, stated in other words, markets (the supply and demand for gold) prove in practice stronger than legislation.

It has, as a matter of fact, always seemed to me in thinking about the real function of money or currency that the Jews understand the significance and meaning of the elementary truths enumerated above better than we do, and I advance it as a probable reason why they are the world's greatest financiers and likewise why so many of them are numbered among the world's greatest philanthropists.

BOOK REVIEWS

Mine Rescue Work and Organization. By H. F. Bulman and Frederick P. Mills. Cloth, octavo, 182 pages, illustrated. Price 12s. net. London : Crosby Lockwood & Son.

There are employed in mining operations throughout the world over six million persons, and of these there are engaged in the working of coal more than the combined totals of all those engaged in other classes of mining, such as exploitation of ores of iron, copper, gold, non-metallic minerals, etc. The value of rescue apparatus at collieries has become so generally recognized that in the principal coal-mining areas Government regulations demand that self-contained breathing appliances be available for use if required at the mine. Accidental ignitions of timber or explosives in metalliferous mines may produce conditions akin to those which exist when an explosion or underground fire occurs at a colliery, and it may be said that the useful application of mine-rescue apparatus is likely to extend far beyond the circles for which it was primarily designed. A committee appointed on the suggestion of the Home Office to investigate the types of breathing apparatus used in coal mines under the chairmanship of Mr. William Walker, the Chief Inspector of Mines, suggested in 1918 that the question of applying the rescue regulations to mines under the Metalliferous Mines Regulation Act should be taken into consideration when any new legislation relating to these mines is introduced. On two occasions the Cumberland rescue station has been called upon for assistance at iron ore mines, and a colliery brigade saved the life of one man gassed by carbon monoxide. For nearly ten years at the examinations for certificates of competency as colliery managers there have been always placed before the candidates questions on rescue work, a subject of growing importance.

Students and others who have to deal with the subject under discussion will find the work of Messrs. Bulman and Mills a helpful publication. The Government regulations on the provision of apparatus at mines and at rescue stations and the course of training for rescue brigades are explained in detail.

It is useful for central rescue stations in the British coalfields to serve a number of collieries situated at a distance of not more than 10 miles in direct line from each station.

At these centres there are provided special facilities for the training of teams from each colliery, which has thus available, in case of accident, men well acquainted with underground conditions at the mine. Their efforts in dealing with an accident would be supplemented by assistance from the central station which is organized on the principles of a fire brigade for prompt turn out when required.

The course of training suggested by the authors is apparently based on practical experience and has doubtless given excellent results, but in the course of fourteen lessons for teams sent from collieries for training there seem to be several points open to criticism. The men are asked to see that provision is made at their collieries for telephonic communications, suitable road for motor fire engine, and good foundation for engine, etc. Details are given of weight and dimensions of motor pump, and it is pointed out that hydrants and hose should be inspected weekly. Would not an official communication from the central mine rescue and fire brigade station direct to the manager of the mine be a better method of dealing with matters of this character, than placing them in the hands of half a dozen men whose primary object in attending the course of instruction is to make them capable of acting efficiently in an irrespirable atmosphere?

The various types of respiratory apparatus and accessory appliances are well described, but no information is given of the Meco apparatus, and the geophone, of which there is a detailed account, does not appear to be of the type familiar to a large number of mining engineers who had experience with Tunnelling Companies of the Royal Engineers during the late war. This instrument, described by Major Standish Ball in the Proceedings of the Institution of Mining and Metallurgy, 1919, not only magnified any sound passing through solid rock but indicated with great accuracy the direction of point of origin. A brief account of the method of utilizing the geophone underground would add to the value of the book under review.

That aeroplanes will be utilized "sooner or later" for the transport of men and apparatus from rescue station to a mine on occasion of disaster, as suggested by the authors, appears to be very doubtful. The difficulty of obtaining a suitable landing place, "an area of 75 acres" near to the mine as mentioned, is not the only factor to be considered under present requirements. When there is an urgent call for assistance a motor-car would be far superior to an aeroplane in quickly reaching a mine within 10 miles of a rescue station.

The authors show a sound and practical knowledge of their subject, and as a text-book, *Mine Rescue Work and Organization* may be recommended to the attention of the mining community.

STANLEY NETTLETON.

Problems in Land and Mine Surveying. By DANIEL DAVIES. Second edition. Cloth, octavo, 355 pages, illustrated. Price 12s. 6d. net. London: Charles Griffin & Co., Ltd.

Civil engineers are fairly well supplied with manuals on surveying applicable to their work; mining engineers are not. The really good all-round book on mine surveying has still to be written; it will be received with open arms when it is. While awaiting its tardy arrival we must be grateful to those authors who present us with treatises covering some of the ground in a helpful way, as is the case here. The first edition, reviewed in these columns in July, 1918, had 276 pages, 145 diagrams, and 400 questions, of which 291 were worked out. The second edition has 355 pages, 195 diagrams, and 550 questions, of which 350 are worked out. Several minor corrections have been made, and the scope of the book has been advantageously extended. Many of the problems and diagrams were originally published in *The Science and Art of Mining*, a periodical well known to students of coal mining; and the book is intended principally to assist the young colliery engineer. The most numerous problems given are those involving calculation of areas, use of trigonometrical ratios, and mensuration, with many others dealing with amount and direction of dip, co-ordinates, errors, faults, levelling, scales, etc. Noticeable additions are: loose needle surveying in the presence of iron, azimuth by solar observation, conventional signs in plan-making, operation of levelling with a dumpy level, methods of booking levelling notes, and a dial survey of a steeply inclined shaft and drift with plan and section plotted therefrom.

For obtaining areas by co-ordinates the author uses the rule: multiply the total latitude of each station by the algebraic sum of the departure of that traverse or

draft and the one following; the sum of these products divided by two is equal to the area of the closed traverse. From the professional standpoint a better rule is: multiply the algebraic sums of the total latitudes (or departures) of every two adjoining stations by the algebraic differences of the total departures (or latitudes) of the same stations; the algebraic sum of the products is double the area. The solar observation example has no explanation appended to it, making it difficult of comprehension by a student; moreover, decimals of seconds are quite superfluous in an observation which usually is not expected to give the true azimuth at best nearer than to 1 minute, and the inadvertent insertion of the declination instead of the codeclination value in one part of the calculation makes it puzzling to the uninitiated.

Approval must be accorded to the instruction that "bordering should be neat, but not unduly elaborate; otherwise appreciation of a well-executed plan may be lost in admiration of the border." Still, students like to spread themselves a bit in the matter of embellishments when it comes to titles, north points, and borders; and enthusiasm for artistic draughtsmanship, even of a rather florid type, is not a bad sign, and should not be too severely repressed.

The book is pleasantly produced, and, within its scope, should be most helpful to students; it should also be of assistance to teachers in furnishing them with a collection of worked and unworked problems suitable for class exercises.

ALEX. RICHARDSON.

Field Mapping for the Oil Geologist. By C. A. WARNER. Cloth, octavo, 145 pages, illustrated. Price 13s. 6d. net. New York: John Wiley & Sons. London: Chapman & Hall, Ltd.

The rapid growth of the petroleum industry has brought with it a corresponding increase in the amount of technical literature dealing with all matters pertaining to oil finding, and the last nine months especially have seen the production of many useful volumes in this connexion, mainly from America. As not unfrequently happens, however, such a literary boom brings with it certain publications which are neither up to the standard of excellence nor of the specific value of contemporary works, and at the outset we are bound to say that this little volum suffeers in these respects.

Firstly, it is somewhat overshadowed by the recent volume by Cox, Dake, and Muilenburg on "Field Methods in Petroleum Geology," reviewed in the June number of the MAGAZINE, which covers practically the same ground, though in much more detail; secondly, as an exposition of field methods, even simply as an outline of first principles, it is sadly inadequate, since much that is of fundamental importance in geological mapping and subsequent interpretation of structures is omitted. Further, the general foundation of the subject which the author sets out to construct is unfortunately made unsafe by extreme brevity of treatment, and without some previous knowledge and experience by way of supplement, it is rather doubtful whether a mere perusal of this work would afford the reader the requisite theoretical grounding in his subject.

The text consists of 145 pages, of which roughly 63 are taken up with tables of constants, geological fundamentals, and index, thus leaving only 82 pages in which to dispose of the subject matter; the latter is dealt with under five chapters, the first being a study of field conditions, the second dealing with maps, their value and interpretation, the third discussing field-mapping and methods, the fourth, mapping instruments, and the last containing details of meridian determination and the tables above referred to. With regard to the first chapter there is little to remark beyond the fact that a discussion of such a broad phase of the subject, when limited to seven pages, cannot possibly be more than the barest summary; for instance, the author might well have extended his remarks on oil-seeps and their examination; far too great importance is, we fear, paid to surface indications of petroleum, so frequently suggesting escape of oil rather than storage in subterranean pools. In Chapter II the study of geological and topographical maps is somewhat stereotyped, as are the illustrations which include the inevitable landscape and contour map reproduced from the inside cover of the United States Geological Survey folios; this particular illustration seems to be a *sine qua non* in American literature of structural geology, as is the case with several other illustrations repeated from time to time in different volumes; such reiteration suggests lack of imagination and does not tend to the creation of a well individualized work.

In the third chapter on field mapping and methods, the author embodies the results of personal experience in geological surveying, and although brief, much useful information is offered. The remarks on correlation of unfossiliferous strata, however, are unfortunate, since the use of vertical sections, implying uniformity of conditions over wide areas, must be extremely limited, uniformity being the exception rather than the rule in most countries. No mention is made of petrographic methods of correlation under such circumstances, methods which are far safer than those dependent on mere lithology and which might well be applied to the Red Beds mentioned by the author. The chapter also includes an abstract of Griswold and Munn's paper on certain oilfields which illustrate the working of isochore maps (U.S.G.S., Bull. 318), and concludes with a few hints on writing geological reports; we are glad to note in the latter connexion that the author insists on a degree of brevity commensurate with the amount and importance of the information to be submitted; professional reports so frequently present the appearance of small textbooks that the advice is particularly apposite.

The remainder of the volume is devoted to a discussion of certain instruments used during preliminary survey, and includes information on the telescopic alidade, Brunton pocket transit, and aneroid barometer, followed by notes on meridian determination and various reference tables. The book will, we think, probably make its greatest appeal to American geologists and others engaged in oil-production in that country, since its teaching is based almost entirely on American practice; even if its scope were wider, it is doubtful whether in its present size and form it would command a ready sale in this country at the prohibitive price at which it is published.

H. B. Milner.

Mechanical Drawing. By John E. Jagger. Third edition, cloth, quarto, 251 pages, illustrated. Price 15s. net. London: Charles Griffin & Co., Ltd.

The object of this book, the result of many years of practice and study, is to provide notes, observations, and examples to enable a student to learn how to read drawings, make a simple working drawing, and apply the knowledge gained in his future work. It is intended for students who have not the opportunity to serve in a drawing office, but who should know something of office processes and methods. The ability to read a machine drawing correctly, and to infer considerations not actually expressed in line and curve, is for the mechanical engineer just as important as the ability to analyse a mine plan is for the mining engineer, and no pains should be spared to acquire such facility.

Beginning with instructions on draughtsmanship, the author goes on to tracing, photo-copying, and principles of projection. Then follow a series of dimensioned designs, ranging from a simple cast-iron bracket to a tool-holder for a planing machine, and a chapter on materials used in mechanical engineering. In addition to the numerous illustrations, the book contains much textual information, comprising formulæ, tables, descriptions, and examples for working. It is, therefore, a great deal more than a book on drawing only; and one which engineering students will undoubtedly find useful. By way of suggestion, it might be an increase to utility to include an example of a small lay-out, say, a motor driving a line-shaft from which power was taken off for a few machine tools, for the purpose of leading the student up to the important field of general planning and organization.

Pumping by Compressed Air. By Edmund M. Ivens. Second edition. Cloth, octavo, 266 pages, illustrated. Price 22s. New York: John Wiley & Son; London: Chapman & Hall, Ltd.

Mr. Ivens undertook the study of this subject in the first instance with a view to obtaining information for his own needs. He had the opportunity to install and test a number of air-lifts operating under varied conditions, and thought the data he had gathered as the outcome of his experience and reading were of sufficient interest to condense and publish. To the first edition have been added some thirty pages of text, and several illustrations, formulæ, and tables; the added matter consisting chiefly of operative results.

The first of the fourteen chapters deals with pumping by the action of pistons; the second, with the displacement pump; the third, with the return air system; the next five with the air-lift; the following four with compression generalities, compressor efficiency, compressors, and flow of air in pipes; the thirteenth with the flow of water in pipes; and the last with a

description of a water-works pumping installation. As will be seen, the air-lift, which is by far the most common method of pumping by compressed air, comes in for extended notice. Mining men will be interested in the system of working sulphur deposits developed by Mr. Herman Frasch. The sulphur is liquefied either by melting or by dissolving, and pumped up into settling tanks. The well is cased to a short distance below the junction of the overlying strata with the sulphur bed, and through this the air-lift piping is carried down well into the bed. Steam is admitted into the casing, and melts the sulphur. The mixture of molten sulphur, hot water, and steam is then pumped to the surface. With regard to air-lifts in general, it might be well to bear in mind the author's opinion that "an air lift improperly designed and installed is one of the most criminally wasteful means of pumping known."

The book is well supplied with illustrations, and data, both theoretical and practical, valuable to anyone desiring information on the subject of pumping by compressed air.

☞ Copies of the books, etc., mentioned under the heading "Book Reviews" can be obtained through the Technical Bookshop of *The Mining Magazine*, 724, Salisbury House, London Wall, London, E.C. 2.

NEWS LETTERS

TORONTO

September 12.

METALLIC PRODUCTION OF ONTARIO.—The returns of the Ontario Department of Mines for the first six months of 1921 show a marked decline in the value of the metalliferous output of the province, with the exception of gold and lead. The total value was $11,363,652, as compared with $22,101,580 during the corresponding period of the previous year. In common with other industries mining is experiencing the effects of a poor market, and the general lowering of commodity prices. The output of gold shows a slight increase, being valued at $5,761,504, as compared with $5,690,504, while the production of silver has declined in quantity from 4,474,322 oz. of the value of $5,077,028 to 4,277,762 oz. valued at $2,552,125. The production of the precious metals was much curtailed during the first quarter of the year by the shortage of electric power, and the output of gold for the full year now that conditions are more favourable promises to establish a new high record.

PORCUPINE.—An interim report of the Hollinger Consolidated, covering the first seven months of the year, presents a highly satisfactory showing. The net profit for the period was $2,339,921, as compared with $2,074,025 for the corresponding period of 1920. The total income was $5,125,050, as against $4,012,242, and the total expenditure $2,785,129, as compared with $1,938,218. The average tonnage milled per day was 2,406 tons, as compared with 1,906, and the number of men employed had increased from 1,103 to 1,369.

The Dome Mines is carrying out an extensive plan of exploration to ascertain the extent of the large ore-body encountered on the 10th level, which has been found to continue downwards for more than 300 ft. The workings are being deepened, but it has not been decided how far the shaft will be put down. A new ore-body has been found on the 7th level, but whether it is an upward extension of the deposit on the lower levels has not been determined. According to an official statement the Dome is now treating an average of 840 tons daily, with an approximate recovery of $6·17 per ton.

The assets of the Davidson Consolidated have been taken over by a new company, known as the Porcupine Davidson Gold Mines, in which British capital represented by Sir Archibald Mitchelson and John Hambly, is largely interested, capitalized at £1,000,000 sterling. The amount paid was £175,000 preferred stock and £450,000 common stock, in the new company, and £50,000 cash, shareholders of the old company retaining their securities. A sum of £200,000 is set apart for working capital and the mine is now being unwatered preliminary to the resumption of operations.

The annual report of the McIntyre Porcupine for the year ended June 30 shows total net earnings amounting to $1,088,513, as compared with $1,280,232, and a net profit transferred to surplus of $815,530, as compared with $818,020. The ore produced was 171,916 tons, of a gross value of $2,005,672, averaging $11·67 per ton, as compared with 188,835 tons of $2,175,891 gross value, and $11·52 average value for the preceding year. The ore reserves were estimated at 624,422 tons, of the value of $6,392,394, an increase of nearly $800,000.

At the Beaumont, formerly the North Davidson, the ore-body cut on the 150 ft. level has been tapped by a cross-cut at the 300 ft. level, and is being opened up.

The Porcupine area is being considerably extended by operations which are being actively carried on in the outlying districts where many new properties are being developed. These include the Union Mining Corporation and Daly claims lying west of the producing area; the Big Dyke, Ankerite Extension, Porcupine Paymaster, and March Gold toward the south; Allied Porcupine and Porcupine-Keora to the north-east; Gold Island lying east and the Triplex in a south-easterly direction.

KIRKLAND LAKE.—This camp is rapidly increasing in extent and importance, and has recently experienced a considerable growth in population. The production of the Lake Shore for July amounted to $49,155 from the treatment of 1,967 tons of ore, with an average recovery of $24·99 per ton. President Harry Oakes states that the physical condition of the mine is stronger than ever, and that the capacity of the mill has been increased to nearly 70 tons per day. Structural work on the new mill of the Ontario-Kirkland of 100 ton capacity is nearly completed, and it is hoped to have it in operation by the end of the year. A considerable quantity of ore averaging about $15 is in readiness for milling. At the King Kirkland another new vein has been opened up with a pay-streak from 1 to 2 ft. wide, which shows commercial ore on the surface for 200 ft. Camp buildings are being erected on the Queen Lebel, and a plan of exploration and development has been arranged. A vein system of some importance has been found on the surface at the Lebel Lode yielding high assays. Exploration is being undertaken to ascertain the zone of greatest enrichment before putting down a shaft.

COBALT.—The silver-mining industry continues quiet. Economic conditions have improved, though not sufficiently to induce the producing mines which closed down last year to resume work. Production by the Nipissing mine, however, shows a steady increase, a noticeable feature being the amount of cobalt produced as a by-product. During July ore was mined of an estimated net value of $166,363, including cobalt valued at $25,380, and bullion from Nipissing and customs ore was shipped of an estimated net value of $223,057. At the Violet property of the La Rose Consolidated a vein 9 in. wide, carrying high-grade ore, was struck on the 570 ft. level. On being followed it was found to widen out considerably, and to show greater enrichment. A rich vein has been encountered on the O'Brien adjoining, heading towards the Violet. A vein opened up on the 4th sub-level of the Bailey Cobalt shows 2 to 4 in. of high-grade ore, with good silver contents in the wall-rock. The report of the Timiskaming for a period of 18 months ended June 30 shows net production of the value of $179,294, and other income of $51,479, making a total of $220,773. Operating costs and other charges were $366,539, making a deficit of $135,765.

SUDBURY.—The mines and smelter of the International Nickel Co., in the Sudbury district, as well as the refinery at Port Colborne, Ontario, were closed down for an indefinite period on September 1. Operations had been greatly curtailed for some months, and the suspension was not unexpected. The reason assigned was general business depression, and the accumulation of heavy stocks for which a market could not be found. During the war upwards of 2,500 men found employment at the mines and works, but the pay-roll has since been gradually reduced to about 600. The Mond Nickel Co. is now the only one in operation, and it is only working on a very limited scale.

VANCOUVER, B.C.

COMPLEX LEAD-ZINC ORES. — What is likely to be the most far-reaching event of the month is the bonding of the Stemwinder mine and the Ontario group, at Kimberley, from the MacKenzie & Mann interests by the Federal Mining & Smelting Co., a subsidiary of the American Smelting & Refining Co. No details of the terms of the bond have been announced except that ample time has been given to explore the deposits with a diamond-drill. The Federal company had the Stemwinder property under option in 1918, but relinquished the option after doing considerable drilling. It is easy to see that there are a number of conditions that may have attracted the Federal back to the property. In the first place, with lead and zinc prices about half of what they were in 1918, and with money considerably tighter, it is likely that the company has been able to make better terms with the MacKenzie & Mann interests, a concern that has the reputation in this province as being rather grasping; but what may have weighed more than this with the Federal is the splendid development of the Consolidated Mining & Smelting Co.'s Sullivan mine, which

adjoins the Stemwinder, and the fact that the Consolidated company, after spending some three-quarters of a million dollars in experiments, has solved the metallurgical difficulties in connexion with the exceedingly complex ores found in the Sullivan and Stemwinder mines. This ore is a compact sulphide containing galena, zinc-blende, marmatite, pyrrhotite, pyrite, and small quantities of several other minerals and not more than 6% of gangue. The lead and zinc contents vary in different parts of the mines, but at the Sullivan they average in the neighbourhood of 18% zinc and 12% lead, with a low silver content, probably less than 4 oz. per ton. Besides numerous laboratory plants, the Consolidated built and dismantled several commercial plants—the largest had a daily capacity of 600 tons—before a satisfactory process was devised. The following is a bare outline of the process finally adopted and now in use. The ore is ground to about 20 mesh and tabled to remove some of the galena and some of the gangue ; the tailing from the tables is slimed to 200 mesh, and treated in Minerals Separation cells, a mixture of pine oil and creosote being used as a frothing agent. This gives a concentrate containing the bulk of the lead and zinc sulphides, together with a considerable proportion of iron sulphides and small quantities of other sulphides. The tailing from this process consists essentially of pyrrhotite and pyrite and gangue. The concentrate is roasted, and the calcine is subjected to an exceedingly clever, though very complicated process, in which the zinc oxide is dissolved by acid zinc sulphate solution, and the solution is neutralized and the iron, arsenic, and antimony salts precipitated by zinc oxide in a fresh portion of calcine. The solution is then separated from the residue, and is further purified by agitation with atomized zinc, which removes copper and cadmium, and is then passed through a series of electrolysing vats, where about 60% of the zinc is precipitated on the cathodes. The solution, which has become acid once again, is used to dissolve zinc from a fresh portion of calcine. Thus a continuous circuit is maintained, a little chloride being kept in the circuit to precipitate any silver that may have gone into solution. The residue from this process, which consists essentially of lead sulphate, ferric oxide, and undissolved zinc in a complicated form, largely ferrate, goes to the lead smelter, where the lead and silver are recovered. The Consolidated company will give out no details either as to cost or recovery, but one can make a shrewd guess at the latter from the quantity of ore treated and the zinc produced, and it is doubtful if a great deal more than 60% of the zinc content of the ore is being recovered. The lead recovery is much higher. Low as the zinc recovery would seem to be, there is little doubt about the process being a financial success, as last year the Sullivan mine produced more than 90% of the zinc and nearly 70% of the lead outputs of Canada. Improvements are being made to the process from time to time and undoubtedly a much better extraction ultimately will be obtained.

To return to the Federal company, however, the proving up of several million tons of this class of ore in the Sullivan mine and the development of a process to treat it has probably been the principal drawing card to induce the company to re-enter the East Kootenay field. The opportunities of the Canadian lead and zinc market, which at the present time is almost entirely in the hands of the Consolidated company, probably also has added weight to the Federal company's decision. It is stated that if it receives encouragement in its exploratory work the Federal company is prepared to spend $3,000,000 in the development of the property. Drilling has been started and will be carried on until a definite conclusion as to the value of the ore deposit is reached.

Salmon River District.—An event of considerable importance has been the shipment of the first consignment of concentrate from the Premier mine, in the Salmon River district. The concentrate was obtained mainly from the treatment of cullings of ore that already had been shipped. The consignment consisted of 160 tons, valued at $1,750 per ton in gold and silver, giving it a total value of about $280,000. This practically establishes the Premier as the biggest gold and silver mine in the Province. A large body of ore has been developed, and it is stated that the ore-body has been proved by diamond-drilling to a depth of 600 ft. below the lowest workings. Shipments of both high-grade ore and concentrate will be made continuously as soon as the aerial tramway, now in course of construction, from the mine to tide-water, a distance of 11½ miles, has been completed. In the meantime, concentrate will be shipped by road, as in the present instance, and it is probable that the high-grade will be sacked and held ; though

it is possible, if the tramway is not finished and the travel is good, some high grade will be shipped over the snow during the winter.

The Salmon River district seems likely to fulfil its early promises. At least two, and possibly three, other mines will be shipping from the district during this winter. The Fish Creek Mining Co., which has been developing a promising lode on Fish Creek, a tributary of the Salmon River on the Alaskan side of the international boundary, already has made a shipment of some 20 tons of high-grade ore, which it is expected will give a return of between five and six hundred dollars per ton, and the company has some 100 tons of similar ore mined. This ore is being held until better shipping facilities are available. The Alaskan Government is building a good trail to the mine, and by the time this has been completed it is expected that the property will be sufficiently developed to be in a position to make regular shipments. Up to the present all the ore that has been taken out has been mined from open-cuts, but a tunnel is being driven to cut the ore-body at a depth of 50 ft. below the outcrop, and this will give cover for operations during the winter. A permanent camp has been established, and work will be continued steadily through the winter.

The Silverado group, which has recently been purchased by a Vancouver syndicate headed by J. J. Coughlan, the ship-builder, is situated on a mountain across the river from the town of Stewart. A narrow vein heavily impregnated with freibergite has been traced by open-cuts between elevations of 2,000 and 4,200 ft. Some 20 tons of ore has been taken out and sacked. A sampling of this ore by the present owners just before the purchase was made gave an assay return of 1,566 oz. in silver and $2·40 in gold per ton and 14·8% of copper. A tunnel is being driven at the 2,000 ft. level, and a camp is being established at this point. The trails are being improved and brush is being cut. The syndicate will endeavour to construct a light tramway between the mine and tide-water, a distance of 8,000 ft. before the winter sets in, so that operations and shipping may be continued through the winter. Some 500 ft. of snow-shedding is being built. Should this work be completed in time it is expected that small shipments will be made regularly.

The Outland Silver Bar Co., which is developing the Outland group, 25 miles up the Salmon River, is taking out a trial shipment of 50 sacks on pack-horses. This property is 14 miles farther up the river than the Premier, and until a considerable outlay has been made to connect it with existing roads shipping on anything but a small scale is impossible. There are a number of promising prospects in the vicinity, and it is probable that the Provincial Government will construct a trail to serve all, leaving the individual owners to make trails from it to their respective properties.

Besides the foregoing, there are a number of properties in a less advanced stage, while there are many others, such as the Big Missouri and the Forty-nine, on which a considerable amount of work has been done, and in some instances on which considerable ore-bodies have been demonstrated, but on which nothing more is likely to be done until transportation or metallurgical difficulties, or both, have been solved. Taken altogether, the Salmon River district is one of great promise, and there seems to be every likelihood that several mines of importance will be developed.

PERSONAL

JOHN BALLOT is, we are pleased to hear, recovering from the serious illness from which he has been suffering recently.

B. V. BARTON has gone from Victoria to Rhodesia to become assistant general manager of the Rhodesia Broken Hill mines.

Dr. J. COGGIN BROWN is returning to India shortly, and his place at the Department of Commerce and Industry of the Indian Government at Winchester House, London, is now filled by Cyril S. Fox, also of the Indian Geological Survey.

A. G. CAMPBELL has been appointed manager of Broken Hill Block 10 mine.

F. G. COTTRELL is on his way back to the United States from Europe.

CHARLES FRÉMONT was presented with the Bessemer Medal of the Iron and Steel Institute at the recent meeting in Paris.

R. T. HANCOCK has joined the staff at the Keeley silver mines, Cobalt.

Dr. J. A. L. HENDERSON has gone to Canada.

E. G. LAWFORD has joined the staff of the Santa Gertrudis company at Pachuca, Mexico.

GEORGE MACFARLANE has returned from Australia.

H. F. MARRIOTT has left for South Africa.

E. P. MATHEWSON was here from the United States last month, and has since left for Burma.

ARTHUR MORT is returning to Baluchistan.

R. E. PALMER is paying a short visit to Canada and the United States.

C.R. PINDER is back from Mexico.

ALEX. RICHARDSON has returned to Camborne from a tour in the United States and Canada.

FRANCIS SAMUELSON is the president-elect of the Iron and Steel Institute.

WILLIAM SELKIRK, of 4, Broad Street Place, London, [illegible] has taken G. W. GRAY into

partnership. The firm will be known as W. Selkirk and Gray. Mr. Gray has been chief mining engineer at Rio Tinto for the past eight years, and latterly he was assistant general manager for the company.

CHARLES E. STEARNS has joined the metallurgical staff of the Union Minière du Haut Katanga.

J. W. TEALE and H. BLACKMAN, of Bainbridge, Seymour & Co., Ltd., have gone to South America.

A. W. WINCEY, manager of Broken Hill Block 10 mine, has gone to Papua to take charge of the Misima gold mine.

Major CLEM WEBB, founder of the *South African Mining Journal*, died last month.

Sir W. E. GARFORTH, one of the best known English coal-mining engineers, died on October 1. He was a past president of the Institution of Mining Engineers. He did much research work in connexion with colliery explosions, and was to the forefront in devising rescue apparatus.

Dr. HENRY WOODWARD died on September 6, in his 89th year. He was for many years keeper of the Geological Department at the British Museum, but probably an even greater service to science was done by him as editor of the *Geological Magazine* from its commencement in 1864 until 1918. He was an ideal editor, patient and kindly, and helpful to the authors as regards the presentation of facts and arguments in comprehensible and proper manner.

JOHN PEARCE ROE, chairman and managing director of Ropeways, Ltd., of Eldon Street House, London, E.C. 2, died on September 2. He was the son of the late John P. Roe, M.Inst.C.E., of Consett, Durham. He was born in 1852, and he commenced his career early in his father's works at Cardiff. In 1870 he went to the Dowlais Iron Company, and was engaged under the late William Menelaus and Lewis Richards, first in the drawing office, and subsequently as one of the general assistant engineers at the company's iron and steel works and collieries. In 1879, at the request of Mr. Menelaus, then chairman of the Orconera Iron Ore Company, he went to Bilbao to report progress and install provisional appliances for getting the output of the mines on board ship ; on completion of this work he was appointed resident engineer of the company, and in that capacity designed and carried out a large amount of work in connexion with the railways, shipping appliances, loading staithes, dredging, and feeder-transport arrangements to the main line, including heavy inclined-plane work. In 1889 he commenced practice as a consulting engineer at Cardiff, and undertook contracts for transporting minerals by means of aerial ropeways in the Bilbao district. In the following year he opened offices in London, and devoted himself particularly to the development of what is now known as the Roe system of ropeways for transporting material in mountainous countries. He eventually formed a company under the name of Ropeways, Limited, of which he was managing director. This company has, both as regards design and erection, carried out a great number of the most important installations in all parts of the world. In addition to supervising the entire work of the company he practised as a consulting engineer, advising on various engineering matters, and particularly in connexion with the handling and transport of minerals and the like. His biggest piece of ropeway engineering work was the Dorada ropeway, which is by far the longest in the world, that is, 47 miles. It was largely due to his inventions and improvements that the single type of ropeway has reached its present state of perfection. He had recently brought out a couple of inventions which will mark a further important advance in ropeway construction. Apart from the work with his firm, he recently invented a new type of rope conveyor, which has just been put on the market, and up to the last carried out consulting work for various projects, generally in connexion with the mechanical handling of materials. Owing to his undoubted genius in engineering and to his magnetic personality the chief members of the administrative and technical staff have been with his firm for periods of from eighteen to thirty years. This shows the high esteem in which he was held by those in close contact with him.

TRADE PARAGRAPHS

The METROPOLITAN-VICKERS ELECTRICAL CO., LTD., of Trafford Park, Manchester, and 4, Central Buildings, Westminster, send us their circular No. 1440/1, dealing with their water-wheel alternators.

W. T. GLOVER & CO., LTD., of Trafford Park, Manchester, send us their descriptive catalogue of the Glo-Clad electric wiring system. This system is useful in mines and in similar places where it is desirable that the wiring shall be water-tight, gas-light, and acid-proof.

R. B. HODGSON & CO (SHEFFIELD), LTD., of the Sentinel Steel Works, Sheffield, send us an elaborate catalogue of their special steels, containing descriptions of the steels and instructions for use. The firm's " Pinnacle " brands of drill steel are well known among mining engineers.

The BRITISH GRIFFIN CHILLED IRON AND STEEL CO., LTD., of Barrow-in-Furness, and Temple House, Tallis Street, London, E.C. 4, send us their leaflet No. 6, giving particulars of their " Boulton " self-oiling wheel, which is specially adapted to mine-cars and where there are sharp curves in the haulage.

The WESTINGHOUSE BRAKE & SAXBY SIGNAL CO., LTD., of 82, York Road, King's Cross, London, N. 1, send us their catalogue dealing with their system of electro-pneumatic control and safety appliances for mines. The appliances described embody the principles adopted in automatic signalling on railways, and they are already in extensive use in mines in connexion with hoisting plant.

EDGAR ALLEN & CO., LTD., of the Imperial Steel Works, Sheffield (London Office : 1, Victoria Street, S.W.), send us the October issue of the *Edgar Allen News*. It contains articles on modern electric furnaces, as applied in heat treatment, the application of nickel-chrome steel to the manufacture of dredge-bucket pins, and the uses and treatment of special alloy steels in Canada. There is also a description of the largest gyratory crusher made in this country, which was made for the Humber Portland Cement Co., Ltd.

The GENERAL ELECTRIC CO., LTD., of Magnet House, Kingsway, London, W.C. 2, send us their leaflet X2574, dealing with their flame-proof switchgear. They also send us their leaflet OS2569, describing the Osglim electric lamp. In this lamp no filament as used in the ordinary type of electric lamp is employed. It consists of a glass bulb similar in shape and dimensions to the ordinary

...andescent electric lamp and contains the rare gas Neon. In the bulb are fixed two metallic electrodes placed at a short distance from each other, and known as the anode and cathode, the anode being connected to the lamp contact by which the current enters, and the cathode to the contact by which it leaves. When an electric current is applied to the terminals an electric discharge or "ionic bombardment" takes place between the two metallic electrodes from the anode to the cathode. This is visible to the human eye, as light of a characteristic orange colour appearing as a luminous haze over and about the cathode. The light is particularly rich in red and yellow rays, and therefore very visible at a distance. In addition it is pleasant and soft to the eye, owing to the large area of light emission.

F. E. BECKER & Co. (Proprietors, W. and J. GEORGE, Limited), of 17–29 Hatton Wall, London, E.C. 1, are putting on the market a prospecting balance for use in connexion with alluvial tin estimations, invented by Philip Grimley, Assoc.Inst.M.M. This balance, which is on the lines of a steelyard, is designed so that if the concentrates resulting from washing ¼ cu. ft. of ground be weighed on it, the value of that sample in pounds per cubic yard can be read from the beam, which is divided into 10 units, each of which is subdivided into tenths. In addition, the weight of the concentrates can be easily ascertained. Two large and three small sliding weights are supplied. Each of the small weights has a *value* of 4·2 grams. That is, if concentrates weighing 4·2 grams are placed in the pan, the beam will be horizontal when one of the small weights is at 1, or, if the weight of the concentrates be 42·0 grams, the beam will be horizontal when the weight is at 10. One quarter of a cubic foot = 1/108 cubic yard, and 4·201 grams = 1/108 lb. So, for example, if ¼ cu. ft. of ground be washed up and when the resulting concentrates are put in the pan the beam is horizontal with one of the small weights at, say, 3·2, the value of the sample is 3·2 lb. per cu. yd., and the weight of the concentrates is 3·2 × 4·2 grams. If only one of the small weights be used, concentrates of a higher value than 10 lb. per cu. yd. have to be weighed in two or more portions, and the beam readings must be added together. But with, for example, one small weight at the mark 10 on the beam, and another of the small weights at 4, a value of 10 plus 4 = 14 lb. per cu. yd. can be read. Similarly, with the medium weight (which is twice as heavy as one of the small weights) at 10, and a small weight at 3 (as illustrated), a value of 2 × 10 plus 3 = 23 lb. per cu. yd. can be read; or with the largest weight at 10 and one of the small weights at 3, a value of 3 × 10 plus 3 = 33 lb. per cu. yd. can be read. In all the above cases the value in lb. per cu. yd. × 4·2 = weight of concentrates in grams. Further, should it, at times, be desirable to wash samples of ½ cu. ft., then the medium sized weight, at say, the mark 7, would indicate a value of 7 lb. per cu. yd. (Should any of the small weights be used when samples of ½ cu. ft. are washed its beam reading must be halved.) When ½ cu. ft. samples are taken, the weight of concentrates in grains = value in lb. per cu. yd. × 8·4. The apparatus is simple and not likely to get out of order when taken on a prospecting expedition. It weighs, in its wooden box, only 1½ lb., and the dimensions of the box are 15 in. by 4½ in. by 1¼ in. One advantage of the instrument is that it can be carried while prospecting so that the samples can be immediately tested, thus obviating error and misadventure, and giving the required information promptly.

GRIMLEY'S PROSPECTOR'S BALANCE.

SHIPPING, ENGINEERING, AND MACHINERY EXHIBITION

The Shipping, Engineering, and Machinery Exhibition was held at Olympia during the three weeks from September 7 to September 28. A few notes are given here of the exhibits of interest to mining engineers.

EDWIN ELLIS & Co., LTD., of Alpha Road, Millwall, London, E. 14, showed specimens of their "World Brand" wire ropes for shipping, engineering and mining purposes.

The EMPIRE ROLLER BEARINGS Co., LTD., of 13, Victoria Street, Westminster, had an exhibit of their "Empire" roller bearings, with a model truck on rails fitted with them.

G. A. HARVEY & Co. (LONDON), LTD., of Woolwich Road, London, S.E. 7, had a comprehensive show of their galvanized tanks, perforated metal, and woven wire-screens.

WORTHINGTON-SIMPSON, LTD., of Queen's House, Kingsway, London, W.C., showed a number of pumps, including high- and low-lift centrifugal pumps, and also air-compressors.

J. & E. HALL, LTD., of Dartford, Kent, had on exhibit characteristic plants for refrigerating and preserving food and for ice-making and cooling water.

THE METROPOLITAN-VICKERS ELECTRICAL Co., LTD., of Manchester, and Central Buildings,

Westminster, showed a great variety of their products from electric winders to lamps and bell-pushes.

HYATT, LTD., of Thurloe Place, South Kensington, had a stall displaying their flexible roller bearings.

REAVELL & CO., LTD., of Ipswich, showed a number of their air-compressors.

THE UNCHOKEABLE PUMP, LTD., of 3, St. Helen's Place, London, E.C. 3, showed their centrifugal pump in action. This pump is used for handling soft materials in water, and also hard materials, such as gravel and tailings.

THE ATLAS DIESEL CO., LTD., of 35, Surrey Street, London, W.C. 2, exhibited a number of their specialities: a crude-oil engine, air-compressor, rock-drills, and coal pick-hammers.

FERODO, LTD., of Chapel-en-le-Frith, showed their stair-treads and their friction linings for breaks and clutches.

COWLISHAW, WALKER & CO., LTD., of Stoke-on-Trent, had a representative exhibit of the coal-cutting machinery, and their haulage plant for mines.

GEOGE KENT, LTD., of 199-201, High Holborn, London, W.C. 1, showed a great number of measuring instruments, including the Venturi meter for measuring the flow of water or gas.

JOHN KIRKALDY, LTD., of 101, Leadenhall Street, London, E.C. 3, showed many applications of their cooling and distilling plants, which are nowadays used extensively at mines for a variety of purposes.

W. H. DORMAN & CO., LTD., of Stafford, made a special show of "Flexstel" piping, the universal joints of which will withstand very high pressures. At the same stand VISLOK, LTD., demonstrated their well-known lock-nut.

THE DE LAVAL STEAM TURBINE CO., of 150, Southampton Row, London, W.C. 2, showed centrifugal pumps, steam turbine, centrifugal blower, etc.

JOHN & EDWIN WRIGHT, LTD., of the Universe Rope Works, Birmingham, and Salisbury House, London, E.C. 2, had a comprehensive exhibit of hemp and wire ropes. These ropes have a large application in mining.

THE PALNUT CO., LTD., of 6, Great St. Helens, London, E.C. 3, showed their safety lock-washer, which was described and illustrated in the MAGAZINE for June last.

SOZOL, LTD., of 20, Copthall Avenue, London, E.C. 2 (which is associated with Minerals Separation, Ltd.), exhibited their anti-rust and anti-corrosion preparations.

The CONSOLIDATED PNEUMATIC TOOL CO., LTD., of 170, Piccadilly, London, W. 1, showed the Hummer rock-drills, the Boyer riveting hammers, and the Little Giant pneumatic and electric drills and grinders.

METAL MARKETS

COPPER.—The standard copper market in London presented quite a steady appearance during September, and fluctuations were within narrow limits. At the beginning of the month prices tended to harden as the result of support believed to emanate chiefly from America, but the upward spurt was not maintained, and subsequent advances were also short-lived. The fact was pretty plainly evident that sentiment was, if anything, pessimistic rather than optimistic, and that conditions were not ripe for any substantial rise in values. The close of the month, however, witnessed a slight revival, and the American quotation also began to harden. The demand from English consumers continued rather unsatisfactory during the month, and although at times the Continent bought moderately, the depreciation in European exchanges tended to restrict the volume of demand from that quarter. Germany, in particular, has been hard hit by the rapid fall in the mark, and reports from the United States would indicate that her purchases there are smaller than recently. In face of the diminished European demand it is rather surprising that the American quotation should have kept firm, especially as consumers there are also taking metal on a small scale only; this, however, is accounted for by the stiff attitude of producers, who seem always eager to push up the quotation at the first sign of improved demand. In the meantime, on both sides of the Atlantic the existence of large quantities of scrap copper and brass continues to have a restraining influence on the demand for virgin metal. Some large deals, however, have recently taken place in British war-scrap, and it looks as if the point of absorption has been brought appreciably nearer. The quarterly reports of the Chino Copper Company, Nevada Consolidated, Ray Consolidated, Utah Copper, and Anaconda Copper Co., all of which are shut down, indicate that they are finding the suspension of operations quite an expensive procedure, and it is to be imagined that most of the mines will reopen immediately the situation looks favourable. In the meantime, however, the large stocks of unabsorbed copper in the United States act as a deterrent.

Average price of cash standard copper: September, 1921, £68 0s. 11d.; August, 1921, £68 12s. 8d.; September, 1920, £96 13s. 4d.; August, 1920, £94 1s.

TIN.—The chief feature of the standard tin market in London during the past month was the upward rise of values during the first few days as a result of the publication of the statistics for August, which indicated a decrease in the visible supplies. This had the effect of infusing an appreciable amount of optimism into the market, and prices rose in consequence. The main factor contributing to this decrease was an expansion in American deliveries, but it was overlooked in some quarters that since American consumption had shown no appreciable improvement, the bulk of the extra metal taken must necessarily have been put into stock; this view, of course, gave the situation a less favourable aspect. In any case, however, the rise in values was not maintained, and by the middle of the month values were back on the level ruling at the opening. It may be mentioned that the United States did not follow the advance here to any extent. Towards the end of the month sentiment again took a more optimistic turn, and, thanks to reports of an improvement in the tinplate industries of South Wales and Pittsburgh, values rose again, but more steadily and slowly. As regards the Continent, Italy, France, and Germany were occasional buyers, but naturally the adverse position of their respective exchanges tended to restrict their takings. During the month the East made fair sales, though sellers there were inclined to hold aloof whenever the market in London was firm. Shipments from the Straits were, however, fairly big during the month. China for various reasons did not feature as a seller.

Average price of cash standard tin: September, 1921, £156 17s. 6d.; August, 1921, £155 8s. 4d.; September, 1920, £270 7s. 3d.; August, 1920, £274 5s. 10d.

LEAD.—Price movements on the London lead market during September were within a comparatively small compass, the general tendency being slightly downwards. A moderate recovery towards the end of the month seemed to be due to covering by bears. On the whole, supplies of lead were less tightly held than previously, and holders of spot in particular relaxed their firm attitude. In consequence, the backwardation, or discount on forward delivery, gradually diminished. It must be admitted that as a result of this the position of the market looks somewhat less artificial than formerly, although, relatively, lead is dearer than either copper, tin, or spelter; and as demand from consumers has latterly shown a declining tendency, it would not be surprising if values were to suffer further. Arrivals of metal from Spain were on a comparatively small scale during the month, probably owing to labour troubles and the diminution of stocks, but this shortage was compensated by shipments from America and even Australia. There was at times quite a good demand from the Continent, but British dealers encountered considerable competition in European markets by American interests. Towards the end of the month, however, the price in New York hardened appreciably to 4·70 cents, and offerings to this country tended to decrease. Germany has been displaying activity as a lead consumer, and in addition to her domestic output finds it necessary to import. It is understood that a syndicate has been formed with a view to reopening some of the Derbyshire lead mines, which were worked during the war, but have since been abandoned.

Average price of soft pig lead: September, 1921, £22 19s. 5d.; August, 1921, £23 5s. 1d.; September, 1920, £35 7s. 6d.; August, 1920, £36 8s. 10d.

SPELTER.—Values on the London spelter market showed a net gain on the month. The opposite might have been anticipated with some reason, as the marked weakness which set in during September in both the Belgian and German exchanges was a possible cause of offerings from those countries. A little metal was certainly forthcoming occasionally from Belgium, but Germany held practically aloof, despite the temptation to realize in London which the mark at 400 must have presented. It would appear that stocks in Germany must be now of quite moderate dimensions, and that domestic consumption can look after a good part of present output, especially as the Silesian smelters cannot be working at full pressure. Further firmness was instilled into the market by the announcement that the stocks in the United States had been reduced during August by some 6,000 tons, which was regarded favourably in view of the fact that stocks there had been piling up for some time past. It is interesting to note that the Belgian output during August was slightly in excess of the July figure, namely, 5,000 tons compared with 4,950 tons. As regards the works in the north of France it is stated that these are working at half pre-war capacity, and do not appear likely to increase their output for some considerable time. A welcome development during the month was an improvement in the galvanizing industry, which brought out more consuming demand for spelter and helped to give the market a healthier tone. In the United States, also, consumers are reported to be taking rather more interest, and the price advanced there also. It looks as if Australasia will be a big producer of spelter in the near future. The Risdon electrolytic zinc works, which were commenced during the war, and have a potential output of 42,500 tons of electrolytic zinc, have purchased some 750,000 tons of concentrates and slimes from the British Board of Trade for treatment. Some Swansea works are contemplating resuming operations.

Average price of spelter: September, 1921, £26 10s. 8d.; August, 1921, £25 8s.; September, 1920, £40 5s. 6d.; August, 1920, £41 19s. 6d.

ZINC DUST.—Prices are lower; high-grade Australian £50; English and American 92 to 94% about £48 per ton.

ANTIMONY.—Values have kept very steady as follow : English regulus ordinary brands, £37 to £40 ; special brands, £38 5s. to £42 ; and 98 to 99% £29 to £32. Foreign in warehouse is about £24 10s. to £25 10s. per ton.

ARSENIC.—Towards the end of the month consumers entered the market fairly freely, in anticipation of the effects of the Key Industries Act, and the price of Cornish white rose from £32 7s. to £43 per ton, delivered London.

BISMUTH.—The quotation is unchanged at 7s. 6d. per lb.

CADMIUM.—Business is quiet at about 6s. per lb.

ALUMINIUM.—Values have remained practically unaltered. Domestic producers quote £120 for home and £125 for export, while foreign metal is apparently still obtainable around £100 f.o.b. Continent.

NICKEL.—The tendency has been a little easier, the quotation being £185 to £190 per ton.

COBALT METAL.—The price has weakened slightly to 14s. per lb.

COBALT OXIDE.—Quotations are lower on the month, black being priced at 10s. 9d. and grey at 12s. per lb.

PLATINUM AND PALLADIUM.—Platinum has been rather firmer, manufactured metal being quoted at £20 10s., and raw at £19. Palladium is steady, with manufactured material priced at £18 to £20 per oz., and raw at £14 to £15.

QUICKSILVER.—Values are lower on the month, the leading interests having reduced their quotation to £9 10s. per bottle. At the moment the market is steady.

SELENIUM.—The price is steady at 10s. 6d. to 13s. per lb.

TELLURIUM.—Sellers still quote 80s. to 90s. per lb.

SULPHATE OF COPPER.—The price is unchanged on the month at £30 to £32 per ton for both home and export.

MANGANESE ORE.—There has recently been a firmer tendency in the market for Indian grades, owing to the rise in the rupee, and the present quotation is 1s. 4½d. per unit c.i.f.

TUNGSTEN ORE.—The market is very quiet, with the quotation for 65% WO_3 none too well maintained at 12s. 6d. to 13s. c.i.f.

MOLYBDENITE.—Sellers of 85% molybdenite continue to quote 37s. 6d. to 42s. 6d. c.i.f.

CHROME ORES. — The present price is about £4 7s. 6d. c.i.f.

SILVER.—The market was quiet at the beginning of the month, but later Chinese and Indian buying caused prices to advance. The quotation for spot bars opened on September 1 at 37¾d., rose to 39⅛d. on the 6th, reacted to 38¾d. on the 8th, advanced again to 39⅝d. on the 13th, and after weakening to 39⅜d. on the 15th, took a definitely upward turn till 43⅜d. was reached on the 27th. The price closed at 42⅝d. on the 30th.

GRAPHITE.—Quotations are rather nominal, and there is no change to report, Madagascar 80 to 90% being still £20 to £25 per ton c.i.f.

IRON AND STEEL.—It cannot be said that much progress is being made in getting the pig iron trade into full swing again. Of course, the old stumbling-block is the high price of fuel, which in turn prevents ironmasters from bringing prices of pig iron down to more reasonable levels. True, the price of Cleveland foundry is now down to 120s., which was the official minimum price fixed some time ago, but even this figure consumers show little disposition to pay, especially seeing that they can obtain supplies from the Continent at much lower levels. The total number of furnaces blowing in the Cleveland district at the present time is only seventeen out of seventy-two. A welcome feature of the semi-finished steel business is the elimination of Continental competition, British makers now being able to book orders at prices below those asked by the makers across the water. In finished steel, however, British producers have a long way to go before they can compete, but the tendency is downwards, and further drops are anticipated before long. Of course, if fuel—and consequently pig iron—came down, we should no doubt see substantial reductions in steel prices. As regards export, makers have been cutting prices to get business, but, with the exception of the far East, few markets are showing much interest.

THE MINING DIGEST

A RECORD OF PROGRESS IN MINING, METALLURGY, AND GEOLOGY

In this section we give abstracts of important articles and papers appearing in technical journals and proceedings of societies, together with brief records of other articles and papers; also notices of new books and pamphlets, lists of patents on mining and metallurgical subjects, and abstracts of the yearly reports of mining companies.

STUDIES OF TRANSVAAL TIN DEPOSITS

Memoir No. 16 of the Geological Survey of the Union of South Africa deals with the tin-mining district between Warmbaths and Lydenburg in the Northern Transvaal. The deposits are just north of the junction of the Elands and Olifants rivers, and are some distance away from the better known tin-mining district north-west of Warmbaths. The Memoir is written by Dr. Percy A. Wagner, who was appointed three years ago by the Geological Survey to make special investigations. The tin-mining district, which is the subject of this report, contains producing mines, operated by the Mutue Fides (Transvaal) Consolidated Land and Exploration Co., the Stavoren Tin Mines Co., the Olifants Tin Mines Co., and the Union Tin Mines Co. The particulars of the deposits are not of great interest from the point of view of production, but Dr. Wagner's studies afford him an opportunity of joining in the discussion of the problem of the origin of tin ores. He says the district gives a grand chance to the mineralogist to collect specimens of a great variety of minerals, but this chance is shared by students of Cornish mines. As we have often remarked, the reports on Cornish and other mines seldom make reference to the existence of any but the leading economic minerals, and the mineralogist desirous of discussing origins is usually unable to make any useful deduction until he makes a personal visit. Mineralogists will therefore welcome Dr. Wagner's voluminous report on these deposits. We make quotations from the report, not for the object of giving a description of the deposits, but for the purpose of publishing Dr. Wagner's views as to the origin of the ores.

The mineral deposits are not restricted to any definite horizon or formation occurring in the red granite, the granophyric granite above the normal granite, the granophyre, the granitic rocks above the granophyre, and in the basal quartzites of the Waterberg System. The deposits are all essentially replacement deposits connected with more or less well-defined fractures and joint-planes, cavity filling having played a quite subordinate rôle in their formation. It should be stated that the mineralizing fractures, as a rule, are mere cracks that do not themselves carry ore. The occurrences are as numerous as they are varied, and present such an extraordinary diversity of type that it is difficult to arrive at a satisfactory basis of classification. It is found, however, that the deposits in each of the geological divisions enumerated have more or less well-marked characteristics, particularly in regard to the assemblages of metallic minerals present and the character of the alteration of the wall-rocks. It is proposed to classify them according to the nature of the rock in which they occur, as follows: (1) Deposits in granite; (2) deposits in granophyric granite; (3) deposits in granophyre; (4) deposits in the zone of granitic rocks above the granophyre; (5) deposits in quartzite. It is not to be inferred from this classification that the nature of the wall-rock has been the principal factor in determining the characteristics of the several types of deposit, though it undoubtedly has had some influence. The main cause of the observed differences lies in the fact that, since the various rocks named are regularly super-imposed and the metalliferous vapours and solutions that gave rise to the formation of the deposits undoubtedly travelled upward, each of the divisions represents a certain thickness of rock that had to be traversed before the solutions (gaseous and liquid) could deposit their load. The kind of country rock is thus correlated with the conditions of temperature and pressure under which the mineralization took place. The deposits in granite, which are the lowest topographically as well as geologically, were evidently formed at the highest temperature and pressure, and those in the quartzite at the lowest temperature and pressure, while the deposits in the other rocks were formed at temperatures and pressures intermediate between those obtaining in the case of the deposits in granite and quartzites. These conclusions are in consonance with what is known in regard to the relative temperatures of formation of the principal ore minerals present in the different occurrences, recent investigations having proved that cassiterite is a higher temperature mineral than wolframite or scheelite, and that these in turn are deposited at higher temperatures than chalcopyrite. Thus, the deposits in granite are essentially tin deposits, cassiterite being the only mineral recovered. Wolframite and chalcopyrite are also present, but only in subordinate quantities. The deposits in granophyric granite are cassiterite-scheelite deposits, both minerals occurring in workable quantity. The deposits in granophyre are cassiterite-scheelite-chalcopyrite deposits, scheelite being often more abundant than cassiterite, while in some occurrences chalcopyrite is in excess of both. The deposits also carry bismuth minerals which were not noted in the other classes of deposit. The deposits so far opened up in the granitic rocks above the granophyre yield cassiterite, copper ores, and wolframite. The deposits in the quartzite are also cassiterite-chalcopyrite-wolframite deposits characterized by containing considerable quantities of specularite, which almost without exception is greatly in excess of the economic minerals present. It remains to be stated that, as regards their ore content, the deposits are extraordinarily erratic and, in consequence, difficult and expensive to work, their exploitation having, on the whole, been attended with disappointing results.

The ore occurrences of the area yield a rich and varied assortment of minerals. In all fifty minerals were identified, some of them for the first time in South Africa. For convenience in description the author divides them into primary ore-minerals, secondary ore-minerals, and gangue minerals

[illegible] important of the ore-minerals. The crystals range in size from [illegible] to [illegible] diameter of 1½ inch, very large crystals occurring in some of the pegmatite [illegible] on the farm Mutue Fides and in certain of the occurrences on the farm Stavoren. The mineral is also found in irregular masses. The colour of the crystals varies considerably, the prevailing tints being yellowish-brown and brown. On the farm Stavoren the cassiterite of the Spruit working is of a pale resin colour, that of the Hillside Quarry is reddish-brown, and that of the "C" and "D" occurrences dark-brown or chocolate coloured. The Joe's Luck working on Roodewal yields translucent crystals of pale-purplish colour of the variety known as "ruby tin."

The presence of stannine in the pyritic ore of the wolfram pipe on Stavoren is inferred from the fact that, whereas the ore can be shown by analysis to contain small amounts of tin, no cassiterite is to be detected in it either in the pan or under the microscope.

Primary scheelite is, after cassiterite, the most important ore-mineral. It is confined to the occurrences in granophyre and in the immediately underlying granophyric granite. It occurs in well-formed square bipyramids resembling octahedra, and also in irregular grains and masses. The crystals often attain large dimensions ranging up to 3¼ in. across, while crystals from 1 in. to 1½ in. across are quite common. The scheelite taken from and near the outcrops of the ore-bodies sometimes shows alteration to tungstite. More usually, however, the crystals and grains present a curiously etched and corroded appearance, and there can be no question that the mineral is susceptible to alteration under the influence of the atmospheric agencies. The occurrence of secondary scheelite may here be referred to, since the mineral is not secondary in the sense that tungstite and certain copper minerals are secondary. It occurs in narrow veinlets and stringers, and also in well-formed crystals in the wolframite of certain of the deposits on the farm Mutue Fides, having been derived from the alteration of that mineral, probably through the agency of heated magmatic waters holding calcium in solution. The scheelite differs from the primary scheelite in being of grey or greyish-white colour, whereas the latter ranges in colour from yellowish-grey to yellowish-brown.

Iron-rich wolfram is sparingly present in some of the deposits in granite on the farm Mutue Fides, where it occurs in masses, some of which are as large as a man's fist. The crystal faces, where present, are generally striated in characteristic fashion. The wolframite from most of these occurrences presents a greyish appearance owing to the presence of numerous minute veinlets of secondary scheelite, which follow the cleavage planes of the mineral and occupy irregular cracks. In the wolframite pipe situated in the upper zone of granitic rocks on the farm Stavoren the mineral occurs in blackish-brown masses up to ¾ in. across. In outcrop specimens of wolframite ore the mineral is generally found to be covered with a rough blackish-brown cellular crust, proving that it also is susceptible to atmospheric weathering. Occasionally the crystals are completely replaced by a dark-coloured porous cindery mass composed entirely of iron and manganese oxides. This form of alteration implies the removal in solution of the tungstic oxide originally present. It has been recorded in the Laxey deposit of Lower Burma by Morrow Campbell, who attributes it to the simultaneous action of alkaline water and oxygen.

Chalcopyrite is the only primary copper mineral hitherto identified in the deposits. It has a very wide distribution, and is present in practically all the important occurrences so far opened up. It is most abundant in the deposits in granophyre, in which it is frequently present in sufficient quantity to repay extraction. There is also an important occurrence of chalcopyrite in quartzite on the farm Roodewal. The oxidation of the chalcopyrite occurring in the superficial portions of many of the deposits, and the downward migration of solutions derived from its decomposition, have given rise to a large and interesting assemblage of secondary copper minerals.

Pyrite is abundant in the deposits in granite, pyritization having next to sericitization been the most important metasomatic process involved in their formation. It is less abundant in the deposits in granophyre, where it is subordinate to arsenopyrite, but is also apparently abundant in the deposits in quartzite, judging by the amount of secondary martite and limonite present in the gossans of these deposits. In the pyritic stanniferous greisen of the Mutue Fides mine the mineral is found in crystals of octahedral habit, while in the chloritic ore of the same occurrence it is present in bright pentagonal dedocahedrons of brass-yellow colour. In the lower levels of the Union tin mines pyrite occurs in fine-grained aggregates composed of small interlocking masses.

Arsenopyrite has a wide distribution in the deposits in granite and granophyre, but has not so far been recorded from any of the occurrences in quartzite. It occurs in well-formed crystals, in irregular prismatic individuals, and finally massive. The arsenopyrite of the arsenic working on the farm Stavoren contains small amounts of cobalt, which is probably present as glaucodote (FeCo)AsS. In some of the Stavoren deposits arsenopyrite is so abundant that it was found practicable to erect a plant for the recovery of arsenious oxide, which was successfully operated during the war. The mineral is also very abundant in the lower levels of the Mutue Fides mine.

Molybdenite is fairly common in the occurrences in granophyre and was also noted in one of the workings in granite on the farm Mutue Fides. It occurs in bright bluish metallic flakes, in aggregates of such flakes, and also in lamellar masses. It is particularly abundant in the aureoles of raven-mica surrounding some of the pipes and eyes on the farm Stavoren. From one of the workings several tons of picked molybdenite ore were actually recovered.

Specularite is fairly abundant in some sections of the Mutue Fides mine and very abundant in many of the workings in quartzite on the farms Roodewal and Stavoren. In the Mutue Fides mine and certain sections of the Union tin mine it occurs in the form of ordinary lustrous micaceous hematite, but most of the occurrences in quartzite yield a dull black variety of the mineral.

Galena occurs in minor quantities in the pyritic tin ore of the Mutue Fides mine in association with zinc-blende, chlorite, fluor-spar, and calcite. It is the product of a later period of metallization than the cassiterite and associated minerals. It is also found in several of the occurrences on Stavoren. Here the mineral occurs partly in large well-formed crystals—combinations of the cube and octahedron—and

partly in irregular masses associated with beautifully coloured violet and bluish-violet fluor-spar. The galena at one of the workings on Stavoren contains up to 50 oz. of silver per ton.

Other primary minerals mentioned by Dr. Wagner in his paper are zircon, magnetite, bismuthinite, galeno-bismutite, blende, and graphite. The secondary ore-minerals mentioned are tungstite, cuprotungstite, scorodite, bismutite, chalcocite, covellite, bornite, native copper, malachite, azurite, cuprite, tenorite, chrysocolla, chalcanthite, olivenite, cerussite, martite, and limonite. The gangue minerals are quartz, chalcedony, felspar, raven-mica, tourmaline, fluor-apatite, sericite, kaolin, lithomarge, chlorite, fluor-spar, calcite, and ankerite. Raven-mica is the rabenglimmer of Saxony, and it is found also at St. Just, Cornwall; it is a lithium-potassium-iron mica.

One of the most noticeable features of the various occurrences is the constant and intimate association of cassiterite with quartz. The mineral is almost invariably found enclosed or partially embedded in the earlier quartz where it has not completely replaced it, and though often found replacing felspar there can be no question that in a great majority of cases the cassiterite has selectively replaced the quartz in preference to felspar. This is very noticeable in certain of the occurrences in granite, in which the original quartz of the rock has been almost completely replaced by cassiterite, whereas the felspar, except where partially sericitized, is unaltered. It was also observed frequently in the deposits in granophyre and in the deposits in quartzite. In explanation of the phenomenon it may be pointed out that tin and silicon are very closely allied, both belonging to the carbon group in the periodic classification, so that one would expect the compounds of the two elements to be intimately associated in nature. Even more important, however, is the fact that cassiterite and quartz have practically the same molecular volume, 21·9 in the case of the former as against 22·8 in the case of the latter. The replacement of quartz by cassiterite in preference to felspar would thus involve a minimum expenditure of energy.

Emphasis is laid by Dr. Wagner on the important rôle played in the formation of the mineral deposits by fissures and joint planes. No distinction is made between these, as the more pronounced fissures appear to be of the nature of master joints. Fissures trending in all directions are met with in the several types of country rock, but only those trending in certain directions are ore-bringers, the productive fissures being clearly those that were accessible to the metalliferous vapours and solutions at the time of mineralization. A knowledge of what directions of fissuring are favourable and what directions are unfavourable is thus of the utmost importance to those engaged in the search for new deposits in the area, whether in virgin ground or in the workings of the existing mines. The author gives the results of his observations in this connexion.

Dr. Wagner then discusses the origin of the mineral deposits. The first point relates to the source of the metalliferous vapours and solutions that gave rise to the deposits. In regard to this point it is evident that the deposits are connected genetically with the intrusion of the main mass of the Bushveld granite, and since some of them pass without interruption from the granite into the overlying rocks and in the deposits in granite all the evidence points to the prevalent direction of movement of the mineralizing solutions (gaseous and liquid) having been upward, the source of these is clearly to be sought in some deep-seated and probably at the time incompletely consolidated zone of the granite underlying the mineralized area. Whether the metals contained in the solutions were extracted from the granite by the agency of mineralizers, as has been suggested for certain tin deposits by Vogt, or whether they represent primary constituents of the mother liquor of that rock, is not relevant to the question at issue, since, as Taber has pointed out, there is no essential difference between (1) the transfer of ore-minerals through the agency of mineralizers set free during the final stages of the consolidation of an igneous magma and (2) the solution and transportation by mineralizers of the metallic minerals originally dispersed through a rock-mass. The N.N.E.–S.S.W. and N.E.–S.W. fissures in the granite appear to have been the only channels that had direct access to this deep-seated zone in the granite. From them the solutions were fed into the W.N.W.–E.S.E. and N. by W. fissures in the overlying rocks in which all four sets were ore-bringers.

The formation of the pegmatites, in which some of the ore-bodies occur, and the deposition of the various ore and gangue minerals clearly represent successive stages in the final phase of consolidation of the Red Granite, the progressive change in the chemical nature of the magmatic emanations having been clearly coincident with a progressive decrease in their temperature. It is now generally recognized that the crystallization of pegmatites involves the co-operation of water and other mineralizers, and takes place at temperatures not far removed from 575° C., the crystallographic inversion-point of quartz. This may be taken to represent the upper temperature limit in so far as the mineral deposits are concerned, since it is improbable that the temperature at any subsequent stage exceeded that prevailing during the formation of the pegmatites; an inference that would agree with the conclusion tentatively reached in regard to the quartz of the second generation in the deposits in the granophyre, namely, that it is α quartz which crystallized below 575°. Of the earlier-formed ore-minerals specularite—the only metallic mineral present that has been proved in any of the deposits to be older than cassiterite—cassiterite, wolframite, molybdenite, and scheelite, are all characteristic of deposits formed at high temperatures. It may be safely concluded, therefore, that the temperature during the deposition of these minerals was well above the critical temperature of water, namely, 358° C. They must thus have been deposited from gaseous solutions, or, in other words, under pneumatolytic conditions, using the term "pneumatolytic" in its strictest sense. Following Iddings and McDonald this period of mineralization may be referred to as the secondary pneumatolytic phase to distinguish it from the primary pneumatolytic or pegmatitic phase during which the pegmatites were formed. Raven-mica, tourmaline, and quartz (second generation) are also assigned to the secondary pneumatolytic phase, but to an earlier stage than the ore-minerals

The next phase of mineralization, during which chlorite, sericite, quartz, pyrite, and chalcopyrite were deposited, has all the characteristics of hydrothermal metasomatism at moderate temperatures. It is not known whether the

[illegible] during this period exceeded the critical [illegible] of water. It is possible, however, that the temperature may have been above 358° at the beginning of the period and below 358° at the end of the period, which would imply a change in the state of the solutions from gaseous to liquid. To this phase the designation "early hydrothermal" may be applied. It corresponds with the propylitic phase which McDonald has distinguished in the phase of the Leeuwpoort lodes. During the fourth phase of primary mineralization, in which galena, bismuthinite, blende, fluor-spar, calcite, and chalcedony were deposited by heated aqueous solutions, fairly low temperatures—probably not far removed from 150° C.—must have prevailed. It may be referred to as the "late hydrothermal phase" and corresponds with McDonald's phase of carbonitization.

Through being brought by denudation into the zone of weathering all the deposits have suffered secondary alteration by oxygenated surface waters, with the resultant formation of oxides, carbonates, secondary sulphides, kaolin, and chlorite. In certain of the deposits these changes, which are in progress at the present day, have been attended with very important results. This final phase will be referred to as the "phase of alteration" by cold descending meteoric waters.

Correlating the successions of the ore and gangue minerals in the several types of deposit with what has been stated in regard to the physical conditions prevailing during the different periods of mineralization, the history of the deposits may be summarized as given in the accompanying table:—

		Prevailing Temperature.
Pegmatitic or Primary Pneumatolytic Phase.	Deposition of pegmatitic felspar and quartz, or pegmatitic felspar alone.	About 575° C.
Secondary Pneumatolytic Phase.	*Stage I.*—Deposition of raven-mica, quartz, and probably tourmaline. *Stage II.*—Deposition of specularite, cassiterite, wolframite, molybdenite, scheelite, arsenopyrite, and fluor-apatite.	<575° C. >358° C.
Early Hydrothermal Phase.	Deposition of chlorite, sericite, quartz, pyrite, chalcopyrite, some fluor-spar, and probably bismuthinite.	
Late Hydrothermal Phase.	Deposition of galena, zinc-blende, fluor-spar, ankerite, calcite, quartz, chlorite, and probably secondary scheelite.	About 150° C.
Phase of Alteration by cold descending Meteoric Waters.	Formation of chalcocite, covellite, copper oxides, bismutite, tungstite, cerussite, martite, limonite, kaolin, and secondary chlorite.	Ordinary atmospheric temperature.

It is of great interest to record that the first four phases, which, as indicated, are practically the same as those made out by McDonald in the lodes of the Leeuwpoort tin mine, also correspond very closely with the four periods of crystallization that Brögger discriminates in the pegmatite dykes of the Christiana region, namely:—

(1) The phase of magmatic consolidation during which the essential minerals of the pegmatites crystallized.
(2) The principal pneumatolytic phase.
(3) The phase of zeolite formation.
(4) The phase of carbonate and fluo-carbonate deposition.

It appears not improbable that on further investigation most tin-tungsten-copper deposits will be found to have much the same history as those under review, but it will probably rarely be so easily and completely decipherable. The confusion that has arisen in the past in regard to the respective rôles of pneumatolysis and hydatogenesis in the formation of such deposits has been due to failure to recognize that in a great majority of cases there have been successive periods or phases of ore deposition, each characterized by certain assemblages of minerals, the different phases probably corresponding with definite ranges of temperature.

While there can be little doubt that the later-formed ore-minerals (pyrite, chalcopyrite, bismuthinite, galena, and blende) were deposited by the agency of heated magmatic waters, there is considerable uncertainty in regard to the nature of the vehicle or carrier that was responsible for the introduction of cassiterite, scheelite, and wolframite. The intimate association of cassiterite with fluo- and boro-silicates in many of the classical tin deposits of the world, coupled with the experimental proof by Daubree and Deville and Carron that at red heat the vapours of stannic chloride and stannic fluoride can be decomposed by steam with the deposition of cassiterite, led to the development of the well-known pneumatolytic theory, according to which cassiterite is generally introduced in the form of volatile stannic fluoride. It must be admitted that where fluorine and boron minerals are abundantly present this theory accords admirably with all the observed facts. Of recent years, however, a number of important tin-tungsten deposits have engaged the attention of geologists, in which topaz, tourmaline, and allied minerals are conspicuous by their entire absence or their extreme rarity. The Mutue Fides–Stavoren deposits belong to this category.

Coggin Brown and W. R. Jones, in discussing the origin of the deposits of Tavoy in Lower Burma, which in their more typical development contain neither topaz nor tourmaline, have independently suggested that the place of fluorine may have been taken by sulphur and arsenic. More recently Morrow Campbell has suggested in respect of the same deposits that highly siliceous heated water (he speaks of a quartz-water mixture) was the carrier of both wolframite and cassiterite. In support of this contention he quotes Verbeeck, who refers to a hot spring in Malacca that deposits siliceous sinter containing 0·5% SnO_2; and also points to

the existence of a compound known as silicotungstic acid (SiO_2, $4H_2O$, $12WO_3$) which is readily soluble in water. Campbell brings forward no absolutely conclusive evidence in support of his views. He assumes, for example, that the same agencies that brought about the greisenization of the granite surrounding the Tavoy veins introduced the cassiterite and wolframite, but gives no reasons for believing such to have been the case. This is the very point in regard to which uncertainty prevails in the case of the Mutue Fides–Stavoren deposits. Extensive greisenization or sericitization has here taken place, presumably through the agency of heated water, but the main period of sericitization post-dated the introduction of the earlier ore-minerals, and there is, as already pointed out, no evidence to show that the deposition of cassiterite was accompanied by sericitization. The only fluorine minerals present in the Mutue Fides–Stavoren are fluor-apatite and fluor-spar. The latter was only introduced at a comparatively late stage in the formation of the deposits and may thus be ruled out. Fluor-apatite, on the other hand, which is sparingly present in some of the deposits, appears to have been formed contemporaneously with the earlier minerals, proving that fluorine compounds were active at this stage in the formation of the deposits, and incidentally affording evidence in support of the commonly accepted pneumatolytic theory. Then, again, specularite, which occurs in several of the deposits in granite and is very abundant in the deposits in quartzite, is known to be readily formed by the interaction between ferric chloride in the vapour state with steam, whereas the direct replacement of quartz by specularite which is frequently observed would be very difficult to explain on the supposition that the iron had originally been in aqueous solution. To the absence of tourmaline the author attaches little importance, for in his experience the association of cassiterite and tourmaline, as a rule, is purely accidental, the latter mineral being generally of earlier introduction. In some deposits, however, boron appears to have been the active agent. Thus, in the remarkable tin occurrences of the Seward Peninsula, Alaska, described by Knopf, boron is actually combined with tin in the rare minerals paigeite and hulsite, while boro-silicates and other boron minerals are abundantly present.

Whatever the nature of the vehicle, it is quite clear that it was capable of reacting very readily and vigorously with quartz and felspar, since even where, as appears frequently to have happened, cassiterite was deposited in crystals of quartz and felspar in drusy cavities, it is never merely found encrusting these minerals, but is always partially embedded in them, and in numberless instances there is evidence of its having replaced them. The cassiterite was thus evidently deposited as a result of mutual chemical reaction between the compound in which the tin was contained and quartz and felspar. It is quite possible that the compound was stannic tetrafluoride and that the cassiterite was deposited by the direct action between it and quartz according to the equation—

$$SnF_4 + SiO_2 = SnO_2 + SiF_4,$$

since Daubree was able to synthesize cassiterite by the action of stannic chloride ($SnCl_4$) vapour on heated lime. If this reaction was responsible for the deposition of the cassiterite, it is remarkable that no topaz was formed in the case of the felspar, and that the stanniferous greisen of the Mutue Fides mine contains not a trace of fluorine. It may have been, however, that the physical conditions prevailing may not have been suitable to the formation of topaz or other fluo-silicates and that the silicon tetrafluoride, which is a gas, passed upward, together with any other gaseous fluorides that may have been formed, and gave rise in the originally overlying rocks at a higher level and at a much lower temperature to the formation of fluor-spar. Much the same reasoning would apply to the scheelite and wolframite, for tungsten also forms a fluoride WF_6 with a boiling point of only 19° C., so that it is a gas at ordinary temperatures. The theory outlined appears, at any rate, to be quite as plausible as that of Campbell, which would make a heated aqueous solution of silica the carrier, for if cassiterite had been deposited by a solution of this nature it would be very difficult to explain the occurrence of the mineral embedded in absolutely fresh and unaltered orthoclase, when it is well known that the latter is very readily attacked by solutions of the nature postulated. Further work will doubtless throw more light on this vexed question, which in the present state of our knowledge it would be idle to pursue.

Dr. Wagner passes to the consideration of vertical ranges of the economic minerals and the prospects of their persisting at depth. The lowest deposits geologically are those in granite on the farm Tygerpad No. 2,300, and the highest geologically as well as topographically those in quartzite on the farm Kwarriehoek No. 1,818. Assuming that the quartzite-granite contact originally extended northward to a point vertically above the Tygerpad workings at the same inclination at which it is seen to dip southward below the Makeckaan plateau, an assumption the propriety of which is open to serious question, then the deposits at present known would represent a vertical range of about 2,700 ft. Of the various ore-minerals present, cassiterite, wolframite, chalcopyrite, pyrite, and specularite have the greatest vertical range, being found throughout the whole series of deposits from those in granite to those in quartzite. The vertical range of the primary scheelite, on the other hand, is limited. It has not been observed in any of the deposits in granite, quartzite, or the upper zone of granitic rocks, and appears to be confined to those in granophyre and granophyric granite. The lowest deposits in which the mineral occurs are those in the Acre Patch workings on Gaasterland, and the highest are the "B. 1" pipes on Stavoren, the difference in level between the outcrops of these deposits being 415 ft. The actual vertical extent of the scheelite, which is evidently very much greater, unfortunately cannot be calculated owing to the uncertainty as to the angle at which the granophyric-granite granophyre contact originally extended northward, and the fact that nothing is known in regard to the downward limit of the scheelite in the granophyric-granite.

Arsenopyrite has so far not been recorded from any of the deposits in quartzite and the same applies to galena and blende. In how far this is due to the fact that only one deposit in quartzite has been worked to even a moderate depth is not clear. Had any of the minerals named been present in considerable quantities in the deposit so far opened up it could, however, hardly have escaped detection.

A very important problem relates to the depth to which the cassiterite is likely to persist. In

[illegible] very little light upon. The investigations of Malcolm Maclaren on the tin mines of Cornwall have placed it beyond reasonable doubt that temperature is the governing factor in the deposition of the mineral, which is evidently only formed within certain definite limits of temperature. These limits correspond in each case with a definite vertical range, which would clearly be determined in turn by the temperature gradient in the enclosing rocks at the time of deposition; so that the temperature gradient really determines the limits within which cassiterite is precipitated from ascending gaseous solutions. [This view has been put forward independently by Morrow Campbell in the paper entitled "The Origin of Primary Ore Deposits," read before the Institution of Mining and Metallurgy in October, 1920. Chapter VI of the present Memoir was written in May, 1920.] In some of the Cornish mines the vertical ranges of cassiterite and the other ore-minerals present have been fairly accurately determined. In the area with which we are dealing the only mineral concerning which anything is known in this respect is scheelite, and even as to its vertical extent there is complete uncertainty. In regard to the range of the cassiterite nothing is known. It may safely be assumed, however, since the metalliferous solutions travelled upward and the temperature gradient was probably fairly uniform throughout, that within the limits previously indicated, the higher a deposit is situated geologically the greater is the depth below its outcrop to which cassiterite is likely to extend. In other words, as regards their persistence at depth, the deposits in the rocks above the Red Granite are more favourably placed than those in that rock. This does not, of course, imply or postulate that a deposit opened up, say in the upper portion of the granophyre, will be found to carry ore continuously all the way to the underlying granite, and then extend downward in that rock, but refers merely to the vertical range of the mineralization. Even in the granite, however, prospects of the tin persisting at depth are favourable, if one may argue by analogy with the only tin-tungsten-copper deposits that have so far been worked to considerable depths, namely, those of Cornwall. In the Cornish deposits it has been established definitely that primary depth zones exist. In the East Pool mine, for example, the downward succession of the economic minerals is roughly as follows: copper ores from the surface to 140 fathoms; wolframite from 140 fathoms to 200 fathoms; and cassiterite from 140 fathoms to 340 fathoms in the south-dipping lodes and possibly to 450 fathoms in the north-dipping lodes. The copper zone is thus succeeded by a tungsten-tin zone and this by a tin zone. In a more recent report on the central mines of the Camborne–Redruth area Maclaren, summarizing his views on the limits in depth of profitable tin-working in that district, points out that in most instances there is a marked falling off in tin-content at an average depth below the granite-killas contact of about 200 fathoms, or some 360 fathoms below the surface; only in one case, the well-known Dolcoath ore-body, did productive ore extend much below this; even this has failed at about the 500 fathom level.

If the same zones exist in the area under review, then it is clear that the Mutue Fides–Tygerpad deposits are near the bottom of the tin-tungsten zone and have not even entered the tin zone proper. It is also relevant to observe that the Zaaiplaats deposits of the northern Waterberg tinfields, which appear to be situated at an even lower horizon with regard to the source of the metalliferous vapours than the Mutue Fides deposits, have been worked to a vertical depth of over 400 ft. As the greatest vertical depth so far attained in any of the workings in granite in the Mutue Fides area is only 135 ft., there is thus every likelihood of the cassiterite persisting far below the limits so far reached. Here again, however, there is absolutely no assurance as to the continuity or workability of any particular occurrence at depth, for the deposits in granite are quite as erratic as those in the overlying rocks. The extraordinary patchiness of deposits of this type is to be attributed to the fact that the principal ore-minerals were introduced by gaseous solutions that travelled along narrow joints and fissures under high pressure and apparently rushed from point to point where favourable conditions to deposition offered, leaving the intervening stretches absolutely barren. The conception of the deposition having taken place from gaseous solutions under high pressure will also serve to explain how very considerable quantities of cassiterite could have been introduced from what in many instances are mere cracks.

As regards depth at which the mineralization took place, the present topography of the tinfields probably bears no relationship whatsoever to that in existence when the deposits were formed. At that time the area was covered with a considerable thickness of sedimentary and igneous rocks belonging to the lower division of the Waterberg System. What the thickness of these rocks may have been there is no means of ascertaining. The thickness of the basal or Rooiberg series in the Makeckaan plateau is about 1,200 ft., and that of the overlying volcanic series of the Waterberg System about 800 ft. This, however, probably only represents a small part of the original thickness of the volcanic series, which in the Middelburg District of the Transvaal, where it attains its maximum development, has a thickness of 8,000 ft. It appears unlikely for various reasons that the volcanic beds were ever anything like so thick in the area with which we are dealing, but there is no positive evidence that they were not. All that can thus be said in regard to the depth of cover at the time of mineralization is that it was not more and in all probability considerably less than 9,000 ft.

It has been shown that the mineral deposits are later than the quartzites and conglomerates of the Makeckaan plateau, which have been correlated with the Rooiberg series, the lowest member of the Waterberg System. The evidence available in the area under review does not enable one to assign more accurate limits to the period in which they were formed. There can be no question, however, that the deposits are products of the epoch of widespread mineralization, following the intrusion of the main mass of the Bushveld granite.

It remains to inquire why the mineral deposits should be situated where they are in a zone about 3 miles wide striking in an N.N.W.–S.S.E. direction. In regard to this question there is nothing definite to go upon and it would be idle to discuss it. The fact that tin-tungsten deposits the world over are connected with anticlinal and domal structures suggests, however, that the position of the mineral belt may have been determined by an anticline in the originally overlying Waterberg beds.

THE NORTHAMPTON LEAD DISTRICT, W.A.

On several occasions the lead-mining operations in the Northampton district, West Australia, have been the subject of articles or notices in our pages, the last occasion being in March, 1919. The properties have been worked for many years by the Fremantle Trading Company, which is allied to the Golden Horse-shoe Company, of Kalgoorlie, but owing to the comparatively low grade of the ore and its irregular occurrence, adverse economic conditions often cause stoppages. Last year F. R. Feldtmann, one of the members of the West Australian Geological Survey, made an examination of this district, and his preliminary report is issued in the Annual Progress Report of the Survey just published. We quote Mr. Feldtmann herewith.

Northampton township, the centre of the mining district, is situated 27 miles direct north of Geraldton, or 34 miles by rail. The new township of Galena is situated immediately south of Murchison River, about 31 miles (45 miles by road) north of Northampton and about 8½ miles (12 miles by road) N.N.E. of Ajana, the terminus of the railway from Geraldton.

The metalliferous district consists of an elevated tract of country, the present surface of which is strongly undulating, where the removal of the overlying Jurassic strata has exposed the crystalline rocks. The southern portion of this area of crystalline rocks, which consists largely of garnetiferous gneiss or gneissic granite, has been surveyed by W. D. Campbell, whose map, published in a Bulletin published in 1910, shows the southern end of the main belt to be about seven miles due east of Geraldton. The northern extension of this belt has not yet been determined, and in view of the economic importance of these rocks a broad survey of this portion of the gneissic belt is highly desirable. From hasty observations made on the road from Northampton to Galena, it appears probable that the gneissic rocks extend without a break to and beyond the Murchison River, with the possible exception of the high Binnu sand plain. How far they extend eastward along Murchison River has not been determined, but they are known to occur at the 10 Mile Pool. The length of the metalliferous belt, if continuous, is therefore at least 70 miles, the maximum width being probably about 15 miles. The belt, however, is very irregular and the average width is probably considerably less.

The gneiss is cut by a number of basic (greenstone) dykes, striking nearly north-north-east, and by a greater number of pegmatite dykes or veins, with, so far as could be determined, similar strike, as have also the lodes. The lodes are closely associated with these dykes, but their relationship to the basic dykes is purely structural, the lines of fracture along many of which these dykes made their way forming lines of weakness during subsequent periods of shearing. On the other hand, the formation of the ore-bodies appears to be closely connected with the introduction of the pegmatites, which probably extended over a considerable period, the earlier stages of which were marked by high temperatures, as shown by the wide development of garnet in the gneiss and also, though but sparsely, in some of the pegmatites and the formation of tourmaline in a few of the pegmatites and their ultra-acid varieties, such as certain of the quartz reefs. The formation of the ore-bodies took place during the final stages of igneous activity, under lower temperature conditions. The occurrence of lead, zinc, and copper deposits as the final products of granitic magmas is by no means uncommon in other countries. In prospecting for new lodes it is advisable to examine closely the immediate neighbourhood of the greenstone and pegmatite dykes.

The gneissic rocks are pale to fairly dark greyish rocks, usually fine in grain, which proved to be garnetiferous wherever examined. The ferromagnesian appears to be chiefly biotite, possibly chloritized in places. Pegmatitic facies of these rocks, with large felspars and garnets, occur. In some places the gneissic structure of the rocks is well marked, in others the rocks are compact and massive, the only traces of a gneissic structure being a slight parallelism of the composing minerals. Occasional zones of sheeted or laminated rock occur in the gneiss, marking lines of intense shearing and probably corresponding to the laminated jaspers so commonly associated with the goldfields greenstones and, in places, with the Pre-Cambrian sediments. The general strike of these sheeted zones is nearly north-west; they were apparently formed prior to the introduction of the basic dykes and the pegmatites.

The basic dykes are for the most part coarse to fine-grained massive epidiorites, from dolerites, but they probably range from intermediate-basic to ultra-basic in composition. Their most remarkable feature is the general uniformity of their strike, which round Northampton averages about N. 32° E.; they appear to be nearly vertical. They are of great length, and, on the average, of considerable width, several of those examined being 60 or 70 ft. wide in places, and Gregory mentions some as attaining a width of 180 ft. Being harder than the surrounding gneiss they usually form prominent outcrops, a rounded outline being characteristic of the weathered outcrops and boulders. Among those lodes, which for a part of their length at least occur along the margins of basic dykes, are the Wheal Ellen, Gwalia (south lode), Unaring, Derby Syndicate (Loc. 325), Wheal Beta, and Yandanooka at Northampton, and the Surprise at Galena.

The pegmatites are of great variety. The occurrence of pegmatitic veins apparently as a facies of the gneissic rocks has already been mentioned, but most of the pegmatites undoubtedly belong to the stages of igneous activity immediately preceding ore deposition, and are intrusive into the gneiss. No direct evidence was obtained as to the relative age of these rocks and the basic dykes, but from their composition and close relationship to the lodes they appear to be younger than the basic rocks. The pegmatite dykes are much more numerous and much smaller, as a rule, than the epidiorites, their width usually ranging from a few inches to a few feet, but it is probable that much larger dykes, particularly of the more acid varieties, occur. Their dip appears to be very similar to that of the lodes.

One of the commonest types of pegmatite is a coarse-grained rock, consisting chiefly of felspar and quartz, mainly in graphic intergrowths, with some large and small flakes of a silvery greenish-grey mineral, probably vermiculite; flakes of graphite are common in some specimens and are probably contemporaneous with the other minerals composing the rock. In some localities the felspars are white, in others, such as the Baddera and Victoria mines, they

[illegible] Aplitic forms of these rocks [illegible]. Specimens of pegmatite of this type from the Wheal Alpha mine contain malachite and azurite, deposited in thin films through the rock, as well as in one specimen, in a vughy veinlet, probably on the wall of the dyke. A variety from an outcrop on the Gwalia mine contains large felspar crystals in a ground-mass consisting largely of a graphic intergrowth of tourmaline and quartz. A different and much more acid aplitic type of pegmatite occurs in the Baddera and Wheal May mines. It is composed of greyish glassy quartz, containing numerous small pale salmon-pink felspars. Another highly acid type from the Baddera is a rock composed of glassy quartz with fairly numerous small garnets; a few minute specks of mica are also present. Extreme ultra-acid types are represented by some large quartz reefs, carrying very sparsely distributed groups of large tourmaline crystals.

The lodes occupy zones of intense shearing and brecciation in the gneissic granite. Where a shear zone is along the margin of a greenstone or pegmatite dyke, these rocks may also be sheared and brecciated. The strike of the lodes is roughly parallel to that of the greenstone dykes, but is, however, less regular. A few of the lodes, including the Uga, the Baddera branch lode, and parts of the Chiverton, Nooka, and Wheal Alpha lodes, strike approximately north. The Surprise lode, at Galena, strikes nearly north-north-west. The dip is usually north-west, at a steep angle, but in places the lodes are vertical, or even have a slight south-easterly dip. The Surprise lode dips west-south-west. In length the lodes range from about three chains (Derby Syndicate lode) to about one mile (Waneranooka lode), averaging, perhaps, between 30 and 40 chains. The width is very variable, and a distinction must be drawn between the width of the lode-channel or zone of shearing and brecciation, and that of the ore veins or shoots. The lode may contain no ore, even where the shear zone is of moderate width, and shearing and brecciation are fairly well marked, or payable ore may occupy the full width of the channel. The ore-bodies may range in width from a fraction of an inch to 30 ft., or even more. In the Surprise mine sheared rock, carrying veins of galena, occupies a width of more than 100 ft. at the 110 ft. level. In most of the lode-channels the shearing stresses have found relief along one or more planes in a main zone of intense shearing, with the formation of a narrow band of crushed clay (flucan) along the planes; the remainder of the rock in the main zone being brecciated. Shear planes, roughly parallel to the main planes, as well as irregular joint planes, were also formed in the rock for some distance outside the main shear zone.

That the ore-bearing solutions were introduced during a period of relief from pressure is indicated by the numerous vughs, the sugary, or crystalline and glassy character of the quartz, and the coarsely crystalline structure of the galena in the larger veins. In the main body of the lodes, where most affected by the ore-bearing solutions, the rock breccia has been recemented by silica, the cement now consisting of very finely crystalline quartz, coloured greyish by inclusions of partly digested rock, and in places containing minute specks of pyrite. As is usual in lode formations the boundaries of the ore-bodies are ill-defined, and the ore is not necessarily confined to the rock enclosed between two particular planes or [illegible] shear plane, which forms a convenient hanging wall at one point in a mine, may be used as a foot-wall at another point. It is probable that shearing also took place along the lode-channels subsequently to ore-deposition. In addition to the varied directions of the striæ on the shear planes, which in the Wheal Ellen mine are in places vertical, in places horizontal, thus suggesting local movement, the main shear planes are in many places marked by a few inches of crush clay, and by a band of crushed rock and clayey material, which carry no ore even where the lode is rich; moreover, bands of barren schist and occasional joint or shear planes occur in the body of the lode. It is difficult to explain why these should contain no ore, except on the assumption that they are subsequent to ore deposition.

So far as could be judged all the lodes of this district are similar in structure, and, with the exception of the Surprise lode, where barite veins are a conspicuous feature in the ore-shoot, in their gangue, though differing in their degree of silicification. Any classification is therefore necessarily arbitrary. It is, however, convenient to group them according to the proportions of economic minerals present into:—

(*a*) Galena lodes carrying only negligible quantities of blende, copper ores, and pyrites; the Baddera, Surprise, and Wheal May lodes being of [illegible].

(*b*) Galena blende lodes, carrying galena and blende in nearly equal proportions with minor quantities of copper ores (chiefly chalcopyrite), pyrite, and marcasite; the Wheal Ellen belonging to this group.

(*c*) Copper lodes, in which galena and blende, if present, occur only in small quantities; in this group, however, pyrite and marcasite are probably present in fair quantities; the Wheal Margaret and Victoria may be taken as representative of this group.

As stated, this classification is purely arbitrary, the three groups grading into each other through intermediate types. Detailed observations had, unfortunately, to be confined to lodes of the first two groups, as none of the workings on the Northampton copper lodes were accessible and practically all the ore had been removed from the dumps.

In the lodes of the first group the galena occurs usually as veins of coarsely crystalline material along the main shear planes; as coarse octahedral or cubo-octahedral crystals lining vughs and in places associated with glassy or sugary quartz; as veinlets of more finely crystalline material in the body of the lode; or, more rarely, in a fine-grained massive, in places schistose, form, probably a replacement of the rock along narrow zones of intense shearing. In the rich shoot in the Surprise mine groups of coarse galena crystals separated by tiny irregular veinlets of quartz occur over a width of 20 ft. in places. The blende and pyrite usually occur as narrow veins or veinlets filling shear or joint planes outside the main body or in the poorer portions of the lode.

In those of the second group the galena occurs as before, but blende is also found in fairly large masses in the body of the lode as well as occurring as in the first group. Pyrite occurs as in the first group, but marcasite is in places associated with galena in the body of the lode. In addition, finely disseminated chalcopyrite (altering to malachite in the oxidized zone) is fairly common in the more quartzose portions of the lode.

The secondary deposition of galena or blende on

a large scale appears to be very doubtful, no deposits definitely formed in this way being known. As is suggested by their mode of occurrence, rich shoots such as those of the Surprise, Geraldine, and Baddera mines are most likely due to the primary deposition of galena from ascending solutions under favourable conditions. On the other hand, the secondary deposition of copper sulphides on a large scale near water-level is of common occurrence. Whether this has taken place to any great extent in the Northampton lodes it is, in the absence of accessible workings, impossible to say. That a certain amount of secondary deposition has taken place is, however, suggested by the presence of such minerals as covellite and chalcocite, though even these minerals may be of primary origin.

There is every probability of the lodes extending to very considerable depths below the limits of the present workings, and there is no evidence to show that rich shoots may not occur below those hitherto discovered. At greater depths, however, the lead ore may change in character, becoming more compact and finer-grained and containing larger proportions of pyrite and chalcopyrite, and probably, also, of blende in lodes like the Surprise and Baddera. In spite of the number of years since mining first started, the district has not been thoroughly prospected, and the recent discovery of the Surprise lode shows that by careful prospecting other rich lodes may yet be found.

IRON ORES OF NORMANDY

At the meeting of the Iron and Steel Institute held last month at Paris, P. Nicou gave an outline of the present position of France's iron ore resources. The restoration of Lorraine to France, and the elimination of German control from the ore-fields of Normandy, Brittany, Maine, and Anjou, the old provinces constituting north-western France, have put her once more in a strong position metallurgically, and the owners of the deposits are seeking customers in Great Britain. The Lorraine deposits have been described many times, but those in north-western France are not so well known.

We quote from Monsieur Nicou's paper herewith with regard to the Normandy deposits, those in Anjou, Maine, and Brittany not being of as great importance at present.

The iron ores of Normandy, Anjou, Maine, and Brittany are, from many points of view, and particularly from their geographical situation, the most suitable of all the French deposits for British ironworks. All the mines now, or in the future, to be worked are in close proximity to the sea. Those of Segré, in the Anjou ore-field, the farthest from ports of embarkation, are only 85 and 135 kilometres distant by rail from Nantes and St. Nazaire respectively, while the Ferrière and Halouze mines, the farthest south of the Normandy mines actually in operation, are within 75 and 80 kilometres of Caen. Before the war a large number of important German companies had acquired considerable interests in these mines, and a heavy trade with Westphalia had commenced, which militated against all attempts to foster an ore trade with Great Britain. At Caen, more especially, the exports to Germany, which in 1908 amounted to 131,193 tons, had risen by 1913 to 342,281, whereas for these two years the exports to Great Britain had only risen from 81,999 to 144,409 tons.

The Normandy deposits spread over the three Departments of Calvados, La Manche, and l'Orne. Though the second largest deposits in France, they contribute only a small proportion of the total output. In 1920 the proportion of output had fallen to 3·55%. This decrease is due to the reopening of the French mines in recovered Lorraine; and the decrease is even less than might have been expected, owing to the destruction of numerous works and mines in the east of France. Whatever the statistics may portend, the production of ore from the Normandy mines had appreciably increased during the years which immediately preceded the war, and the 1913 output would have justified the hope that in 1914 extraction would have reached a million tons. Great developments were in progress at the Soumont mines, and particularly at St. André and at Barberry, and but for the war the Normandy deposits might well have amounted to several millions of tons annually. A considerable proportion of this output would have been employed at works in the north of France; Halouze and La Ferrière are mines belonging to the Aciéries de France et de Denain-Anzin, and the Isbergues and Denain works of the company would have taken the largest proportion of their output. The Forges et Aciéries du Nord et de l'Est had large interests in the Larchamp mine, and would have mixed the ores from this mine with those from their Pienne concession in Meurthe-et-Moselle, thus securing a particularly satisfactory charge for their blast-furnaces. These three mines, Halouze, La Ferrière, and Larchamp, all situated on the main syncline of Ferrière, had in 1913 produced 373,000 tons of ore, that is, 45% of the whole Normandy production. New works in Pont-à-Vendin and at Dunkerque were similarly to have derived a large proportion of their ore requirements from Normandy. In addition to the foregoing, blast-furnaces in the course of construction in Calvados, in the immediate neighbourhood of Caen, to be provided with steel works and rolling mills, were to draw their supplies from the Soumont mines, and having associated interests in Westphalian works were to exchange ore for coke with the latter, thus accomplishing a purpose towards which British ironmasters ought now to address themselves. Other concessions in which Germans held the great bulk of the shares, or in which, through the intervention of Dutch shareholders, they possessed large interests, were equipped with plant destined to increase their productive capacity and develop an extensive trade with their shareholder customers.

Since the war the situation has greatly changed. The northern works, such as Denain, Isbergues, Valenciennes, and Pont-à-Vendin, have been completely destroyed by the Germans, or so vitally injured that it will take many years to restore them. This is one of the reasons for the notable decrease in the iron-ore production of Normandy. The Caen works, taken over by a company which has eliminated the German element, cannot develop to the extent wished for. Hence the Normandy mines must look for their development to the

[illegible] while [illegible] them [illegible]

The [illegible] either as [illegible] carbonate or hematite. Both may exist simultaneously, as the hematite always passes into carbonate at a greater or less depth. Normandy hematites are at present chiefly mined at St. Rémy, St. André, and May. The St. Rémy ores are the richest of all the Normandy ores, and contain 50 to 55% of iron, 10 to 12% of silica, 3% of alumina, 2·5% of lime and magnesia, 0·6 to 0·7% of phosphorus, and 3% of water. At St. André and May the iron percentage is lower, being between 46 and 51, with 14 to 16% of silica. The other concessions contain chiefly or entirely carbonate ores which have to be calcined. Only 12 to 15 kg. of fuel per ton of ore is required for calcining them, and the yield varies from 75 to 79%. On their withdrawal from the kilns the ores from the three following mines contain: Halouze, iron 48 to 49%, silica 14 to 16%; La Ferrière, iron 47 to 49%, silica 13 to 15%; Larchamp, iron 48 to 49%, silica 14 to 15%. The proportion of alumina varies from 4 to 7% and the lime and magnesia from 3·5 to 4·5. The phosphorus remains between 0·6 and 0·7%. These calcined carbonates are therefore relatively rich, and the three mines in question are just those from which export would be the easier. Soumont ores only yield 45·9% of iron after calcining, the silica being higher than in the ores just described. The ores of Mortain, Bourberouge, and Jurques are very similar to those of Soumont. It will be seen that while the ores are somewhat siliceous, they are, generally speaking, high in iron. Their composition shows that they are suitable not only for making basic pig iron, but also for mixing, while without any fluxes they can make phosphoric foundry pig containing 1·2 to 1·3% of phosphorus, as well as pig iron suitable for open-hearth furnace working. The carbonates are usually porous when calcined, as is shown by their weight per cubic metre. This varies, after calcination, from 1,600 to 1,650 kg., and thus presents a distinct advantage when they are smelted.

Four principal regions may be distinguished, each corresponding with a particular syncline: May, Urville, Falaise, and La Ferrière. The most northerly comprises the concessions of May, St. André, Bully, and Maltot, which were granted before the war. Only two of these are being worked. At May the beds have a dip of 45° and a thickness varying from 4 to 6 metres, but of which only a thickness of 2·5 metres is being actually worked, the remainder being too high in silica. The sinkings carried out by the Société des Mines et Produits Chimiques reach a depth of over 100 metres below the surface and extend underground for over 4 kilometres. A large shaft at Lorguichon, near to the mineral railway connecting the Soumont mine with Caen, has been sunk to a depth of 150 metres and will allow of an annual production of 150,000 tons of ore. This ore is a hematite containing 46 to 47% of iron. In 1920 production had reached 100,189 tons, and fell, owing to the war, to 45,256 tons in 1919. In 1919 it had increased to 62,051 tons. At St. André an almost vertical bed is worked to a depth of nearly 100 metres, and the ore is got from a bed of hematite 2·5 metres thick, overlain by a bed of carbonate not yet being worked. The outputs in 1913, 1919, and 1920 respectively were 89,225, 60,956, and 75,567 tons. The Bully and Maltot concessions have hitherto only been explored by bore-holes. It is along the May syncline that investigations eastward have been pursued to ascertain whether the workable beds of May and St. André extend. The results have been of sufficient interest to warrant the Government granting, this year, a series of concessions extending as far as the railway from Argentan to Mezidon. These concessions at Condesur-Ifs, Fieville, Garcelles, d'Ouézy, d'Ouville, and St. Pierre-sur-Dives cover a greater area than all the others in Calvados put together.

The second syncline, sometimes known as La Brèche du Diable, but more commonly as Urville, comprises six older concessions, Soumont, Perrières, Barberry, Estrées, Gouvix, and Urville. Investigations made in this instance, westward, have led to the prolongation of the syncline being established as far as its outcrop, and have led, since the commencement of the year, to the granting of the Cinglais concession. Of all the concessions of this second basin the most important in every respect is that of Soumont, which supplies the Caen blast furnaces of the Société Normande de Métallurgie, with which they are linked up by a private railway. Here there occurs a seam of carbonate ore having a dip of 30°, which appears from bore-holes sunk to depths of 400 metres, to get less steep as it becomes deeper. So far the seam has been proved for a depth of 200 metres by slopes and roads which have established its continuity and constancy. The ore gives, on calcination, 45·9% of iron, and roads have been driven for several kilometres. Down to depths of 60 metres hematite is found, but below these depths it disappears completely. In 1913 the mine produced 71,637 tons of ore, of which 9,000 tons was imported into Germany and the rest put into stock. Since that date the work done by the new company owning the Caen furnaces (Société Normande de Métallurgie) has been directed to supplying adequate quantities of ore for the consumption of the blast-furnaces, and to making calcining tests, which have yielded excellent results. In 1919 the output of carbonate ore amounted to 40,400 tons, of which 24,042 went into stock and 16,358 was passed through the kilns. By December the stocks had risen to 219,602 tons of raw ore, and 52,223 tons of calcined ore. These stocks were heavily drawn upon during 1920 for consumption at the works. During 1920 Soumont produced 4,339 tons of hematite and 65,322 tons of calcined carbonate. The Barberry concession, in which the German Gutehoffnungshütte held the interest, was naturally sequestrated during the war, and has since been completely idle. In 1913 the production was 16,624 tons of calcined ore from a bed in which only a thickness of 2·5 to 3 metres was worked, to avoid getting a too siliceous ore. Arrangements had been made for the rapid development of this mine, for an output of 300,000 tons, which shows the importance attached by German metallurgists to the Normandy deposits. Soumont, which was also to supply part of the ore needed at the Thyssen works in Westphalia, was in 1914 being prepared for an output of 500,000 to 600,000 tons annually, beginning with 1915. The war stopped this development, but the plant is capable, whenever required, of realizing such outputs. Of the other concessions on this syncline, only the Gouvix mine has been restarted by the Société des Forges et

Aciéries de Firminy, for the purpose of getting ready to supply the Dunes works near Dunkerque. The ore is a carbonate, and calcining kilns have been installed. Extraction has only been of a preparatory nature, and the tonnage has hence been small.

The third Normandy syncline, that of Falaise, is the best known, as it contains the St. Rémy concession, the oldest (having been granted in September, 1875) and the richest. A bed of hematite 2·5 metres, of very uniform quality, overlain by a thickness of about 1 metre of carbonate ore, is worked. The carbonate ore has a purplish colour, and was not formerly worked, although for a few years it has been exploited. The hematite contains 51 to 55% of iron and the raw carbonate 41 to 42%, with 12·9% of silica. The bed is only worked to slight depths—33 metres on an average—below the surface. Production, which in 1911 reached 106,852 tons, fell in 1913, as the result of a long strike, to 77,620 tons. In the year 1920 the output was 78,713 tons, of which 43,218 tons were the richest. The first-named produces only carbonate. Throughout 1919 it was only working part time, and whereas in 1913 its output was 89,896 tons of calcined ore, in 1920 it only produced 18,275 tons of ore, of which 14,588 tons were calcined. The seam has a thickness of 5 to 8 metres, with numerous changes of dip and strike, creating difficulties in working. One shaft is at work, and the ores are transported by an aerial ropeway to the station at Chatelier, 7 kilometres away, on the line from Domfront to Flers. Twelve calcining kilns, with forced draught, have been installed at the mines. The Halouze concession, along the immediate prolongation of the latter, has a somewhat narrower seam, 5 to 7½ metres in thickness. It is worked by two shafts, each 180 metres deep, and by an incline. Actual working is confined to depths not exceeding 130 metres, but provision has been made for extraction at greater depths. There are eight calcining kilns, and a railway 8 kilometres in length connecting the mine with the station at

North-Western France, showing Position of Iron Ore Deposits.

hematite and 35,595 tons were carbonate. The remaining concessions on this syncline, at Ondefontaine, Jurques, and Montpinçon, produce only carbonate of much poorer quality, and with the exception of Jurques, which has been worked by the Société Français des Mines de Fer, have been little developed. At Jurques there appear to be three beds, two of which are workable, but of which only one is at present being worked. It has a thickness of 1·80 metres, and a dip of 55°. The investigations quite recently made at Montpinçon have led to the recognition of only one seam, much faulted and probably unworkable. The description of these three synclines completes the account of the Normandy deposits occurring in the Department of Calvados.

The fourth syncline spreads over the Departments of l'Orne and La Manche, and covers two widely differing regions; the eastern in l'Orne, with the Mont-en-Gérome, La Ferrière, Halouze, and Larchamp concessions, and the western, containing the Mortain and Bourberouge concessions, Larchamp, Halouze, and La Ferrière are at the present time the three most important mines in Normandy, and, with the exception of St. Rémy, Chatelier. The output in 1913 was 152,656 tons of ore. In 1920 only 44,559 tons were produced, of which 40,678 tons were calcined and dispatched. In some places the concession yields a hematite ore, but in small amounts only as compared with the carbonate ore. The mine belongs to the Compagnie des Aciéries de France. At La Ferrière, which belongs to the Denain Anzin Company, the seam is the prolongation of that encountered at Larchamp and Halouze, and has a dip of between 35° and 40° south, which becomes steeper northward before reaching Halouze. Eight kilns are installed for calcining the carbonate ore, and the mine is connected by rail with the St. Bomer station on the Flers-Domfront line. Most of the ore was, before the war, used at the works of the proprietors, but these having been destroyed by the Germans the output has been greatly reduced, and only the requirements of outside customers have been catered for. While, in 1913, 121,650 tons of calcined ore were dispatched from the works, the 1920 output was only 32,500, while the kilns calcined 50,100 tons, the difference being taken out of stock.

Of the other concessions on the La Ferrière syncline, the Mont-en-Gérome mine is not as yet

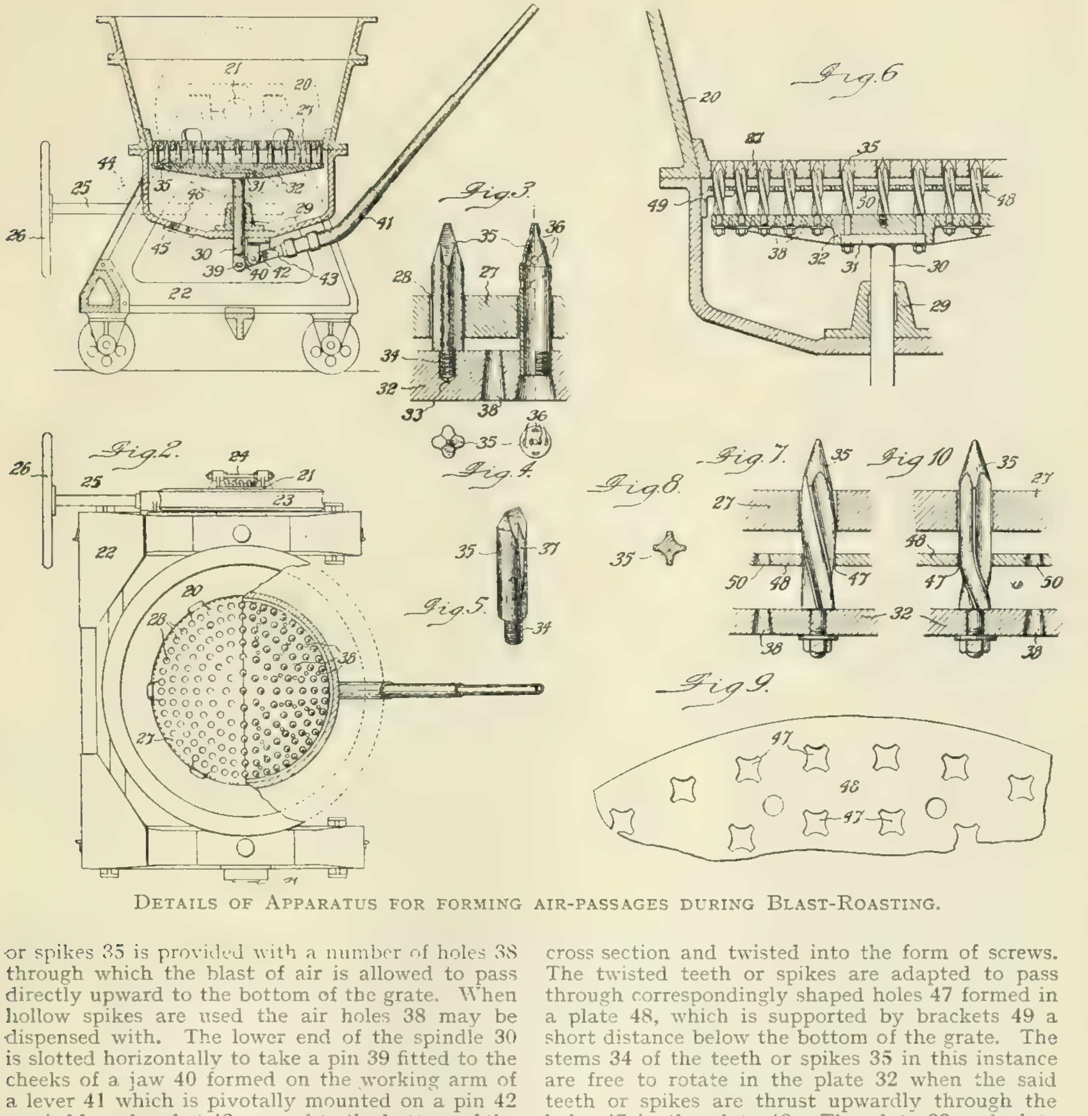
been worked, only trial borings to ascertain the extent of the seam, its thickness and quality, having been carried out. According to the information yielded by these bores, the seam is less important than those just described. At Bourberouge there is a workable seam of 2·5 metres thick, with an average dip of 30°, and at Mortain the thickness reaches 6·5 metres, and the maximum dip is 54°, which becomes steeper as the depth increases. Both these mines, which belong to the Société Française des Mines de Fer, were before the war worked for the export trade. They are connected by rail respectively with the Avranches station on the Domfront line, and Mortain on the Vire line. Kilns were installed, but by 1913 production had only just begun and the output was 34,553 tons of calcined ore at Bourberouge, and 6,833 tons at Mortain. The former mine became flooded during the war up to its adit level; at Mortain the same thing occurred to the lower levels.

Blast-roasting. — British Patent 13,958 of 1920 (146,936), issued to the Mining and Metallurgical Processes Proprietary, Ltd., of Melbourne, as assignees of Gilbert Rigg, of the Broken Hill Associated Smelters, describes an improved apparatus employed in blast-roasting. Mr. Rigg's work in this line is well known, for articles have been published in the MAGAZINE for June, 1918, and February, 1920, and he read a paper before the Institution of Mining and Metallurgy in May, 1920. We quote this patent specification in detail.

The invention refers more especially to means for perforating and thus opening up or breaking the clinker which normally forms immediately over the grates in such operations. In metallurgical operations involving the passage of a blast or current of air through a body or charge of ore upon a grate, it has been found that the layer of material immediately over the grate is usually fused into a more or less impervious cake or clinker and that consequently the passage of air is seriously impeded and frequently rendered irregular and uneven, involving constant attention in the filling up of blow-holes to avoid intense local action. In many cases this results in the limiting of the thickness of the charge to a comparatively thin layer and retards the completion of the operation. It has been found by an examination of the treated charge that the lower layer has fused into a compact mass of clinker, although the upper portions of the charge are not so affected. The object of the present invention is to provide means whereby the layer of clinker or slag formed over the grate is periodically perforated and thereby broken or opened up for the passage of the air blast. This object is accomplished by providing mechanical means by which the layer of clinker or slag is intermittently perforated. These mechanical means preferably comprise a number or series of projecting teeth or spikes adapted to be intermittently forced through the layer of clinker or slag as the same is formed over the grate, thereby perforating and opening it up for the passage of the air current. These projecting teeth or spikes are preferably adapted to work in conjunction with the grate, and in practice the same teeth or spikes are caused to project through the perforations or interstices of the grate, being mounted upon a suitable carrier or member which is adapted to be moved up and down by suitable mechanical means.

An apparatus embodying the features described is illustrated in the accompanying sheets of explanatory drawings. Fig. 1 is a view in sectional side elevation of a pot, as used in the Huntington-Heberlein process, fitted with mechanical devices for perforating the clinker formed over the grate therein. Fig. 2 is a view in plan of Fig. 1, part of the pot being broken away to show details in the mechanical means devised for perforating the clinker. Fig. 3 is a view illustrating two forms of spikes or teeth for use with the apparatus. Fig. 4 is a view in plan of the spikes or teeth shown in Fig. 3. Fig. 5 is a view in perspective of another form of spike or tooth. Fig. 6 is a view in sectional elevation of part of a pot showing a modification in the means employed for perforating the clinker. Fig. 7 is a view in sectional elevation of part of Fig. 6, and shows a modified form of tooth or spike. Fig. 8 is a view in sectional plan of the tooth shown in Fig. 7. Fig. 9 is a view of part of a constructional detail shown in Fig. 6. Fig. 10 is a view similar to Fig. 7, showing another modified form of tooth or spike.

In these drawings the reference numeral 20 designates a pot having trunnions 21 supported on a frame 22 provided with transport wheels of approved form. One of the trunnions 21 is fitted with a worm wheel 23, which gears with a worm 24 carried by a shaft 25 fitted with a hand-wheel 26, which is adapted to be operated to tilt the pot sufficiently to empty some of its contents as desired. A grate 27 is supported at an approved point in the height of the pot, and this grate preferably comprises a cast metal plate having a series of holes 28 formed vertically therein. The grate 27 is preferably mounted removably within the pot to permit of its being replaced by another when worn out or damaged. The bottom of the pot is provided with a centrally disposed hole above which is mounted a guide member 29 for a spindle 30, which is adapted to be reciprocated vertically therein. The upper end of the spindle 30 is formed with a cap or flange 31 which is bolted to the centre of a plate 32 which conforms to the shape, and is somewhat smaller than the interior of the lower part of the pot. The plate 32 is formed with a series the threaded holes 33 which are adapted to take the screwed shanks or stems 34 on the lower ends of a series of teeth or spikes 35. The teeth or spikes are preferably pointed or sharpened on their upper ends and normally project upward into the bottom of the holes 28 in the grate 27. The teeth or spikes 35 may be made to the same shape as, but slightly smaller in cross section than the holes in the grate, or they may be made of such other cross-sectional shape as will permit of the passage of air through the holes when the teeth or spikes are thrust upwardly through. The teeth or spikes may be given a cruciform shape in cross section, as shown in Fig. 4 of the drawing, or they can be made hollow as represented partly in sectional elevation in the right-hand side of the same figure. When the teeth or spikes are made hollow as shown, the plate 32 is bored right through to permit of the air, forced under pressure into the bottom of the pot, passing freely upward to and through the holes 36 formed in the upper end of the said hollow teeth or spikes. The upper ends of the teeth or spikes can be provided with chisel points, and when made of round bar material their sides may be formed with grooves or flutings 37 (see Fig. 5 of the drawings). In order to permit of the uniform distribution of the blast beneath the grate 27 the plate 32 carrying the teeth



Details of Apparatus for forming air-passages during Blast-Roasting.

or spikes 35 is provided with a number of holes 38 through which the blast of air is allowed to pass directly upward to the bottom of the grate. When hollow spikes are used the air holes 38 may be dispensed with. The lower end of the spindle 30 is slotted horizontally to take a pin 39 fitted to the cheeks of a jaw 40 formed on the working arm of a lever 41 which is pivotally mounted on a pin 42 carried by a bracket 43 secured to the bottom of the pot. The power arm of the lever 41 preferably is made up of two or more telescopically connected parts to permit of it being shortened when the pot is to be tilted to empty it of its contents. The connexions between the parts of the power arm of the lever 41 can be made in any well-known manner. The air blast is supplied to the lower part of the pot through a pipe 44 as shown in dotted lines in Fig. 1 or in any other approved way. The lower part of the pot can be cleaned as and when desired by removing the cover 45 on an opening 46 in the bottom thereof.

If preferred the teeth or spikes 35 can be made as shown in Figs. 6 and 7, and means may be provided for effecting a partial rotation of the teeth or spikes when they are being thrust upwardly through the holes in the grate 27. In this last-mentioned form of apparatus the teeth or spikes are made of cruciform or other irregular shape in cross section and twisted into the form of screws. The twisted teeth or spikes are adapted to pass through correspondingly shaped holes 47 formed in a plate 48, which is supported by brackets 49 a short distance below the bottom of the grate. The stems 34 of the teeth or spikes 35 in this instance are free to rotate in the plate 32 when the said teeth or spikes are thrust upwardly through the holes 47 in the plate 48. The plate 32 and plate 48 are provided with holes 38 and 50 respectively to permit of the free passage of the air blast to the grate.

When the lower parts only of the teeth or spikes are twisted as shown in Fig. 10 of the drawings, the teeth or spikes will be partially rotated when their screwed or twisted parts are passing through the holes 47 in the plate 48.

After the charge in the pot has been ignited and the blast turned on, the formation of dense clinker or partially slagged material commences to take place. By means of the lifting mechanism the teeth are forced upwards into this dense layer, which they perforate, thus allowing the blast to pass through. It will be seen that as these teeth are uniformly distributed over the lower surface of the charge, a uniform distribution of air through the charge is effected. The operation of raising the teeth and perforating and opening up the bottom clinker

[illegible] thus [illegible] and a more uniform [illegible] obtainable in the case of blast- [illegible] the treatment of ores for the formation of oxides and the like by the operation of a blast or current of air through a mixture of the ore and fuel it is possible to work with much deeper charges than have hitherto been found practicable.

The addition of atomized water to the air blast can be conveniently made use of in regulating the temperature of the roasting mass. This application is made possible by the uniformity of the blast distribution. Where blast distribution is irregular and patchy the cooling effect of the atomized water would be localized, and give rise to irregular roasting.

Anodes for Copper Deposition.—British Patent 13,572 of 1920 (157,871) contains an interesting discussion of the problems at Chuquicamata as regards the life of the anodes in the electro-deposition of copper. These problems have been referred to on several occasions in the MAGAZINE, and they have constituted the chief subject of study at this copper mine. The patent is granted to the Chile Exploration Company, of New York, as assignees of Colin G. Fink. We quote herewith from the specification.

For efficient and satisfactory use in the electrolytic recovery of copper from copper sulphate electrolytes, an anode should possess certain properties. In the first place it should be of the so-called insoluble anode type, that is to say, it should be to a high degree insoluble in the electrolyte, or in other words, it should possess high resistance to anodic disintegration. In addition the anode should have high electrical conductivity, and a low anodic potential in order to keep the electrical losses as low as practicable. Again, the anode should be of such a character as to permit the ready discharge of oxygen gas therefrom, thereby eliminating or minimizing the undesirable consequences of polarization. In practice it is generally only possible to approximate the ideal condition with respect to each of the aforementioned properties, and accordingly it is necessary in the production of an anode for commercial practice to resort to a compromise of the ideal conditions with respect to these properties in order to obtain an anode possessing the desired properties to a more or less satisfactory degree.

The present invention contemplates the provision of an improved anode possessing in a remarkably satisfactory degree the aforementioned desirable properties, made up of an alloy containing cobalt and silicon. A depolarizing ingredient, such as manganese, is preferably included in the alloy, and, as a result of electrolytic action, provides a depolarizing coating or film for the surface of the electrolode which facilitates the discharge of oxygen gas therefrom. A hardening agent is also preferably included in the alloy, and serves the purpose of hardening the surface coating or film of the depolarizing agent. Chromium may be advantageously used as the hardening agent, and tungsten, molybdenum, and uranium may also be used as the hardening agent.

The improved electrode of the invention is accordingly made up of an alloy of which the principal constituents are cobalt and silicon. In its preferred form the electrode also contains manganese and chromium, together with a certain amount of carbon. Excellent results are obtained with an alloy of the following composition: 11·5 to 13%, silicon, 4 to 6%, manganese, 4 to 6%, chromium, 0·8 to 1·2%, carbon, and the balance cobalt. If desired, 5 to 30 parts of the cobalt content of the alloy may be replaced by manganese, or 5 to 12 parts of the cobalt content may be replaced by chromium, or 5 to 8 parts of the cobalt content may be replaced by nickel, without objectionably altering the advantageous properties of the alloy as an anode material. The proportion of carbon, manganese, chromium, and silicon can be somewhat varied, but in general neither the carbon, manganese, chromium, or silicon should be too low, or the corrosion of the anode will be objectionably increased. On the other hand, the carbon, manganese, chromium, and silicon content should not be too high. A high silicon content results in a decrease in the strength of the anode, and an increase in both its tendency to corrode and in its specific electrical resistance. If the carbon content is too high, the carbon separates out in a graphitic form. The best results are obtained with a carbon content slightly in excess of the amount which can be combined, so that there is a small amount of fine graphitic carbon, such as will give a grey surface to the fracture, but without any excess of graphitic carbon.

The alloys of cobalt and silicon are distinguished from alloys of other more or less similar metals with silicon in their availability for use as electrodes. This distinction, and the advantages of the cobalt-silicon alloys, are due in part to the anodic properties of the cobalt, that is, to its tendency to be deposited on the anode, which distinguishes cobalt from most other metals which deposit on the cathode. The advantageous properties of the cobalt alloys are further due to the peculiar characteristics of the cobalt-silicon alloys. Photo-micrographs of cobalt-silicon alloys containing about 12 to 15 % of silicon indicate that the silicon is in part present as such or in solid solution in the cobalt, while a large part is present in the form of a eutectic made up of a solid solution of cobalt silicide (Co_2Si) in the cobalt and perhaps also of the cobalt silicide itself. The photo-micrographs indicate that the resistance to corrosion may be largely due to the presence of the silicon and of the cobalt silicide.

With anodes of cobalt-silicon alloys and copper cathodes there is a voltage in dilute sulphuric acid of about 1·7 to 2·0 volts at a current density of 20 amperes per square foot of anode surface, and a spacing of 1½ in. between anode and cathode. Also there is a maximum strength against flexure to be obtained with a silicon content of about 12 to 15%. For example, a flexure strength of around 6,200 lb. per sq. in. (unit beam 1 in. square, 12 in. span) has been possessed by electrodes of this silicon content. Both any material increase and any material decrease in the silicon content of the alloy seems to decrease the mechanical strength of the electrode, and in general the greatest strength is obtained at between 12 and 15% of silicon. In its breaking strength the improved electrodes of the invention are to be distinguished from electrodes of iron and silicon, where, for example, a similar content of silicon gives an electrode with a flexure strength of about 1,000 to 1,500 lb. per sq. in. The greater strength of the cobalt-silicon electrodes of the invention, as compared, for example, with iron silicon electrodes, enables a much thinner

anode to be employed without objectionable reduction in strength, so that less space is occupied thereby in the electrolytic tanks or cells. Any considerable increase in the silicon content of the cobalt-silicon electrodes, as above noted, tends to increase both the voltage and the brittleness.

Good results are obtained with a carbon content of about 1%, or between 0·5% and 1·2%, and with a silicon content of from 12 to 15%. Graphitic carbon, as pointed out, is objectionable beyond a certain small amount, but inasmuch as cobalt will combine more readily than iron with a small amount of carbon, it is possible to include such a larger amount without an objectionable amount of graphitic carbon being present.

From investigations made of photo-micrographs of electrodes embodying the principles herein disclosed, it is believed that the improved electrode of the invention owes its advantageous properties to the fact that it is composed for the major part of two constituents. The first of these constituents is more or less soluble in the copper sulphate electrolyte, but possesses good electrical conductivity. The second constituent is relatively insoluble in the electrolyte, but is not a good conductor of electricity. The first constituent appears to be an alloy or a mixture of alloys of the various metallic constituents of the electrode, while the second constituent appears to be a eutectic, probably silicide of cobalt. It furthermore appears from the photo-micrographs that the structure of the anode is made up of particles of the first constituent, which particles are more or less enclosed or enveloped with a coating of the second constituent. The eutectic, accordingly, appears to provide a coating for the alloy particles, which effectively serves to prevent these particles from going into solution at an objectionably high rate, but at the same time this eutectic coating is so shallow or narrow as not to objectionably decrease the electrical conductivity of the electrode as a whole.

The cobalt-silicon anode is of special advantage in sulphate electrolytes containing appreciable amounts of nitrates and chlorides. In such electrolytes lead anodes disintegrate rapidly. Lead anodes stand up more or less satisfactorily in sulphate electrolytes free of nitrates or chlorides, but even in such electrolytes the cobalt-silicon anode of the invention is superior to lead anodes, since the anode of the invention possesses a higher current efficiency than a lead anode and stands up better in all electrolytes including those for which lead is adapted.

The electrode of the invention is of particular value when employed as an anode in the electrodeposition of copper from such solutions as are obtained upon leaching Chuquicamata copper ores. This electrolyte contains primarily copper sulphate, sulphuric acid, and a number of other salts, among which are included alkali nitrates, sulphates, chlorides, and iron sulphates. In addition, the electrolyte may contain small quantities of aluminium, calcium, magnesium, and potassium sulphates.

With an anode of the preferred composition hereinbefore mentioned, it is found that the loss in electrolytes of this character at 20° C. and at 20 amperes per square foot of anode surface, is approximately 0·5 lb. per one hundred pounds of copper deposited, and that the voltage from anode to cathode at this temperature is about 1·9 volts. It is found that higher temperatures give lower corrosion losses, which is in contradistinction to the behaviour of ferro-silicon anodes.

The manganese included in the improved electrode serves the purpose of a depolarizer. In an acid sulphate electrolyte at a temperature of from 10 to 15° C., the manganese goes into solution as permanganic acid. At temperatures of from about 30° C. to 60° C., this permanganic acid formation is practically absent, and instead there is obtained a heavy deposit of manganic oxide on the surface of the anode. In both cases, however, manganese dioxide is precipitated or deposited on the anode, but in the case of the warm or heated solution, the deposit of manganese dioxide is more adherent and there is practically no loss of manganese in the solution. This deposit of manganese dioxide, together with some cobalt oxide, on the anode acts as a depolarizer, and ensures the free discharge or liberation of oxygen gas from the surface of the anode. Moreover, cobalt-silicon anodes made up in accordance with the invention, but without manganese, have a tendency to corrode at the solution surface line, and this tendency is minimized by the addition of manganese to the alloy.

The addition of chromium or other chromium-group metal to the electrode acts to harden the manganese oxide film or deposit on the anode. Thus, the manganese dioxide film is more resistent to abrasion in the case of cobalt-silicon-manganese anodes containing chromium than it is in the case of anodes of similar composition but without chromium, tungsten, molybdenum, or uranium.

It will, therefore, be evident that while certain advantages of the invention are obtained without the inclusion of either manganese or a chromium-group metal in the electrode the presence of both of these materials is desirable, since the addition of these materials imparts to the anode further desirable properties. Thus it is found that the addition of chromium to the anode greatly facilitates duplication of low-loss, low-voltage anodes.

In the production of these anodes cobalt, with its normal impurities, may be employed, including some small percentage of nickel, iron, manganese, and carbon. Good results have been obtained with cobalt containing around 4 to 7% of nickel and iron together. In the production of the anodes the procedure is to melt the cobalt and add charcoal to increase its carbon content, or to simultaneously reduce a mixed oxide of cobalt, manganese, and chromium (or other chromium-group metal). The silicon is then added, together with the manganese to the molten cobalt, but it is found that the addition of the silicon to the cobalt results in a violent evolution of heat, so that care should be taken to avoid the addition of such large amounts of silicon as will result in objectionable overheating. The silicon can be added gradually or as carbide of silicon, or it may be combined with a small amount of cobalt and the resulting alloy or mixture added to the remaining portion of the cobalt. The violent evolution of heat which takes place when the silicon is added to cobalt is a further characteristic of the cobalt-silicon composition which distinguishes it from iron-silicon compositions.

The electrode of the present invention, in addition to its improved property of resisting anodic disintegration or corrosion, possesses in dilute sulphuric acid a relatively low anodic potential. In other words the voltage between the anode and a copper cathode is relatively low, being approximately

from about 1·8 to about 2·0 volts at 20° C. at an anode current density of about 20 amperes per square foot. This feature is of particular importance in the electrolytic production of copper, since it is instrumental in determining the terminal voltage which must be applied to the electrolysing cells. The cost of electrolytically precipitating copper from an electrolyte is proportional to the voltage which must be applied, and from the standpoint of commerical economy it is of the utmost importance that the surface-tension voltage of the anode be as low as practicable. The cobalt-silicon electrode of the present invention, combining as it does a relatively low surface-tension voltage with very effective resistance to anodic corrosion, makes a very durable, economical, and satisfactory anode in the electrolytic precipitation of copper.

The Separation of Minerals.—At the meeting of the Midland Institute of Mining, Civil, and Mechanical Engineers, held in August at Sheffield, Stanley Nettleton read a paper describing his method of separating minerals, based on their varying coefficients of friction. The paper dealt with the separation of stone from coal, but the principle is equally applicable to ore-dressing.

In the preparation of minerals for the market or for metallurgical treatment, it is generally necessary at some stage of the process for a sliding movement to take place on a hard surface of metal or other material. This sliding may take place in screening and in simple transit from one part of the plant to another, and these sliding effects may be utilized in order to separate one class of mineral from its natural associates of lower value. The inclination necessary to cause material to move upon a sloping surface is governed by a number of factors which have received attention from manufacturers of mining appliances, but the question of angle of slope appears to be generally solved by empirical methods. It has been found by experience that small material, say, of ½ in. diameter, requires greater inclination to cause movement than pieces, say, 1 or 2 in. in diameter, and that unscreened mineral which consists of fragments of all sizes down to particles of dust does not move so freely down a sloping surface as mineral which has been classified into grades of approximately equal sizes. The presence of moisture usually tends to hold up unscreened mineral on an inclined surface, but its effect is modified in the case of closely-sized material such as nut coal, ranging from 1 in. to 1½ in. in diameter. As crushing is a prominent feature in ore-treatment, reduction in size of mineral is rarely disadvantageous, and for this reason chutes and screens at metalliferous mines are generally placed at inclinations much in excess of that necessary for free movement in order to avoid the possibility of holding up any of the mineral.

Data on the slope necessary to overcome the coefficient of friction of minerals is meagre, but the subject has been referred to by several authors. Professor Henry Louis states, in "Dressing of Minerals," that "it is necessary to distinguish between the angle at which a mineral just commences to slide, and that at which it continues to slide at a uniform velocity after it has started from rest." He gives the result of determination upon moderately large lumps of various minerals sliding upon a smooth steel plate. From his table it may be assumed that the slope necessary to initiate movement may be anything from 24° to 31¼°, or 4° to 11¼° more than that which will maintain motion after a mineral has commenced to slide on an inclined plane. Materials such as quartz, coal, and limestone vary so much that some information is desirable on the physical character of the specimen tested. Limestones may be soft and friable or hard and semi-crystalline. The term "coal" includes materials varying in specific gravity from 1·15 to 1·45, and of widely different physical character. Gas-coal frequently breaks into fragments of more or less cubical form; cannel coal has often a semi-conchoidal fracture; anthracite breaks very irregularly, and lamellar structure is not unknown in lignitic coal.

Form, size, specific gravity, and hardness may each have an influence on the angle of slope at which a piece of mineral will commence to move or continue to move when placed on a smooth surface. Breakage is a matter of importance in the handling of coal, and the friction coefficient may be a factor used in the dry separation of coal from shale. In order to determine the principles underlying the behaviour of coal and the rocks with which it is associated in the mine, a large number of experiments were made on the lines here indicated. Samples of materials were broken and separated into classes of approximately similar sizes by screening; wire screens with square meshes of $\frac{3}{16}$, $\frac{3}{8}$, and $\frac{5}{8}$ in. were used to make three classes. It should be noted that closeness of sizing is governed to a considerable extent by the form which each mineral assumes when broken. Shales have a tendency to break into pieces in which the length and breadth are disproportionate to the thickness, while pieces of coal and anthracite usually assume a more or less cubical or spherical form. For this reason, on shaking coal and shale over a ½ in. mesh, the shale passing through the screen will contain more pieces over ½ in. in length than is the case with coal-sizing.

A small quantity of sized material was placed gently upon an inclined sheet of plate-glass, which was tapped three times in each experiment. There was then noted the proportion of material which slid off the inclined plane. Results were apt to be rather irregular, particularly near the points at which the material did not move at all, or the whole of it slipped off the glass.

The following is an example of a test. A large number of pieces of Yorkshire bituminous coal were placed on a sheet of glass 36 in. in length at an angle of 22°. In placing material on the inclined surface, each particle was put in contact with the medium over which it was to slide, so that carrying and packing effects were eliminated as far as possible. The size of the coal was through $\frac{5}{8}$ in. and over $\frac{3}{8}$ in. mesh, and the percentages of pieces of coal which moved to the bottom of the plate on tapping in nine experiments in these tests were 75, 85, 75, 70, 65, 80, 70, 75, 70. Average, 74%.

About 700 experiments were carried out on a considerable number of pieces of mineral. Large numbers of pieces were used in each of these experiments and averages were taken, in preference to a small number of carefully selected specimens being used which would have given more concordant results. Owing to the irregular nature of the materials dealt with in practice it was believed that the former method would give the more useful results, although these results would be of a more relative character. It was found from these that

the sliding of minerals over plane surfaces appears to be subject to the following laws : (1) Large pieces of coal have a less coefficient of friction than smaller ones ; that is, when set in motion they will continue to slide over a plane which is at a lower inclination. (2) Material which is freshly broken does not slide so readily over a smooth surface as material which has been standing some time before it is dealt with ; apart from the well-known fact that different minerals have different coefficients of friction.

The force in these experiments tending to move a particle may be taken as the component of the weight parallel to the plate ; that is, the weight multiplied by cosine of the angle of inclination of the plate. The principles deduced have been found equally applicable to the sliding of minerals on steel surfaces.

In introducing his paper, Mr. Nettleton said his object was the separation of coal from shale by mechanical means. If they could have a machine which would deal with the friction effect in such a manner that shale could be picked out of coal, they would have got something of value to the mining community. These friction effects were relative, and not absolute. If they put a quantity of anthracite and shale upon a plate inclined at an angle of 19°, 95% of the anthracite would slide off, but only 5% of the shale ; so that they would obtain a method of separating the anthracite from the shale. But, supposing the slide was taken at 20°, and vibrated so that the anthracite moved, then all the anthracite would be moved off ; but only about 12% of the shale would move. Taking then a case where they had 10% of dirt in an anthracite, they would find all the anthracite would be removed, while only 5% of the 10% of dirt would be removed. They would thus get only 5% of the 10%, a negligible quantity, of dirt remaining in the cleaned coal. These results were taken on the sliding effects upon a glass plate, but glass had the same frictional effects, though in a rather different degree as steel. It would, however, be impracticable to have a long steel slide over which material had to be shot, owing to the cumbrous nature of that arrangement. They could increase the friction by passing the material down a moving surface, such as a belt, so arranged that during the passage over 10 in. of space the dirt would move upwards, say, 50 in. By that effect they would get 60 in. of friction on the belt. The next point would be to obtain some means of removing the material or avoiding colliding effects, and he got over that difficulty by dividing the path of friction into two portions, one in a straight line and the other in a moving surface, which, for practical purposes, was most convenient in a rotating steel disc.

The author exhibited a small experimental model, in which a steel disc, 2 ft. in diameter, was rotated by a motor, and material was fed down a spout on to the disc. The coal went straight forward across the disc, while the shale turned off at an angle. When an arrangement of that kind was fixed up on satisfactory engineering principles, he said, it was possible to get almost a perfect separation of anthracite, say, from associated shale. By using the two sides of the disc, they would double the capacity of the machine, and if they had a vertical shaft it was possible to have a number of discs on that shaft, 6 ft. or 8 ft. apart, and it should then be possible to multiply the efficiency of the machine twenty times. Further reference will be made to this paper in a future issue.

Hyde's Welding Process.—*Engineering* for September 2 contains an account of a process of welding invented by A. C. Hyde, of the Hyde Welding Co., Wolverhampton. By this process two pieces of steel are joined together by means of copper which permeates the surfaces and forms an alloy of iron and copper. The secret of getting copper into such a fluid state as to enable it to penetrate the finest cracks and to start molecular action is to melt it in an atmosphere of hydrogen. The hydrogen reduces any oxide on the iron or steel, and it also has the remarkable effect of making the molten copper as fluid as petrol. The copper immediately spreads over the surface in an extremely fine film and penetrates the space between the parts to be joined. It is stated that the joints obtainable in this way are strong and reliable. Presumably the fluidity of the copper is explained by the principle of surface tension, and scientific investigation of the phenomenon would be of great interest.

Determination of Vanadium.—The *Journal of Industrial and Engineering Chemistry* for August contains a paper describing a method for the determination of vanadium in ores and metallurgical products, written by R. B. Schaal, of the Firth-Stirling Steel Co., McKeesport, Pennsylvania. The author has found the modification of Johnson's method previously used at these works uniformly low. The method here described is believed to meet all the requirements of accuracy, speed, ease of execution, and economy so necessary for routine and general use. The method depends upon the reduction of vanadic acid, by prolonged boiling with strong hydrochloric acid, to the tetravalent condition, and subsequent reoxidation with a suitable solution of potassium permanganate to the pentavalent state. The reaction involved are well known, and may be stated as follows :—

$$V_2O_5 + 2\,HCl = V_2O_4 + H_2O + Cl_2$$
$$5V_2O_4 + 2KMnO_4 + 6HCl = 5V_2O_5 + 2KCl + 2MnCl_2 + 3H_2O.$$

This reaction is found to run to completion with a sharp end-point, in a nearly neutral solution containing a suitable excess of ammonium phosphate, and admits of the presence of large amounts of iron, chromium, molybdenum, cobalt, nickel, uranium, titanium, or zirconium, besides the amounts of manganese usually present in all samples. The colour of ferric chloride is destroyed by the ammonium phosphate. Chromium, because of its deep green colour, tends to obscure the end-point. This fact offers no difficulty to the chemist familiar with the determination of chromium by the ferrous sulphate-permanganate method, the end-point appearing as faint old rose reflections through the green. The use of an ordinary Mazda lamp behind a white screen clarifies the end-point to a remarkable degree, and the use of this device is recommended for all samples containing 3% or more of chromium. Molybdenum has been present in tests to the extent of 10%, and apparently interferes in no appreciable manner. As the reduction of the vanadium by hydrochloric acid is selective with respect to molybdenum, this element remains in the oxidized state and is not affected by permanganate under the conditions obtaining in the titration. Cobalt and nickel have been added in amounts up to 5% of each, the only effect being the production of a slight green colour. Elements whose phosphates are insoluble, or partly so, under the given conditions, notably uranium,

[illegible] steam, cloud the solution, but do not otherwise interfere. If present in appreciable amounts, the precipitates may be removed by filtration. By far the most important effect of the ammonium phosphate is that of converting any excess hydrochloric acid present, above the amount actually needed for the completion of the reaction, into the less highly ionized phosphoric acid, and thus minimizing the danger of reaction between the excess acid and the potassium permanganate. It should be pointed out that excessive cold slows the reaction unduly. If conducted at 20° C., however, the reaction proceeds with a rapidity which leaves nothing to be desired. The end-point does not disappear, as is the case in titrating cold sulphuric acid solutions, so slowly as to leave doubt as to the precise end of the reaction, but becomes permanent at once.

SHORT NOTICES

Estimation of Zinc.—In the *Journal of Industrial and Engineering Chemistry* for August, M. Bodansky gives a method of determining extremely small quantities of zinc.

Concentration Problems.—In the *Engineering and Mining Journal* for August 27, E. S. Wiard commences a series of articles on preliminary roughing concentration by sorting, jigging, and tabling.

Nevada Consolidated. — In the *Mining and Scientific Press* for September 4, A. B. Parsons gives a detailed description of concentration at the mill of the Nevada Consolidated Copper Company.

Electric Furnaces.—In *Chemical and Metallurgical Engineering* for September 7, J. Herlenius writes on electric furnaces adapted to the melting of gold, silver, and other metals of low melting point.

Permanganates. — The *Journal of Industrial and Engineering Chemistry* for September contains a paper by Wilson, Horsch, and Youtz describing the experimental electrolytic production of permanganates of soda and potash from ferro-manganese anodes.

Carbonic Oxide.—In the *Journal of Industrial and Engineering Chemistry* for September, C. R. Hoover gives methods of detecting small quantities of carbonic oxide, small but sufficient to give unpleasant physiological effects.

Aluminium.—In the *Journal of Industrial and Engineering Chemistry* for September, J. H. Capps gives a method for estimating the oxygen content in commercial aluminium.

Cornish Tin Lodes.—The September *Bulletin* of the Institution of Mining and Metallurgy contains a paper by H. B. Cronshaw on the structure and genesis of some tin lodes in the Camborne district.

Octagonal Shaft.—A paper was read at the September meeting of the American Institute of Mining and Metallurgical Engineers by J. L. Bruce, giving particulars of a circular shaft lined with timber arranged octagonally.

Scottish Oil Boring.—At the meeting of the British Association held last month, H. M. Cadell read a paper entitled "Evidence from Recent Bores in the Carboniferous Rocks of Scotland."

Stope-Filling.—A paper on hydraulic stowing in coal mines, by Professor George Knox and J. Drummond Paton, appears in the *Proceedings* of the South Wales Institute of Engineers, just published, and is reprinted in abstract in the *Iron and Coal Trades Review* for September 30.

Flotation applied to Coal.—A paper on the froth-flotation of coal, by F. B. Jones, appears in the *Proceedings* of the South Wales Institute of Engineers, just published, and is reprinted in abstract in the *Iron and Coal Trades Review* for September 30.

RECENT PATENTS PUBLISHED

☞ *A copy of the specification of any of the patents mentioned in this column can be obtained by sending 1s. to the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. 2, with a note of the number and year of the patent.*

10,561 of 1920 (141,733). M. M. Merritt, South Middleton, Massachusetts. Improved electrolytic plant for coating steel wire with copper.

10,573 of 1920 (151,236). W. E. Trent, Washington. A process of treating materials having a carbonaceous content, more especially coal, lignite, and the like, which consists in subjecting the material in a fine state of subdivision suspended in water to the action of a hydrocarbon having the property of forming a dense agglomerate with the carbonaceous particles to the exclusion of the water and non-carbonaceous particles.

10,895 of 1920 (168,097). E. E. Naef, Nottingham. Method of removing sulphur from copper-nickel matte by melting with caustic soda.

10,929 of 1920 (168,098). L. A. Wood and Minerals Separation, Ltd., London. In the flotation of oxides such as cassiterite, introducing carbonic acid gas into the agitated pulp for the purpose of preventing other gangue minerals rising.

12,486 of 1920 (142,847). R. Walter, Villach, Austria. Improved method of making acid-proof alloys of silicon with iron, nickel, and chromium.

13,786 of 1920 (167,863). Allis Chalmers Manufacturing Co., Milwaukee. A roasting furnace subdivided into a number of sections or hearths, separated by doors, and arranged at different levels, each section being provided with an independently operable set of rabbles.

15,278 of 1920 (167,904). R. de H. St. Stephens, Camborne, and A. Ewing, London. Improvements in the construction of rock-drills, particularly in regard to the feed of water by preventing any admixture of air with the water, so that atomization or spraying is prevented, and the flushing out of the hole by the water is rendered more efficient. The tube conveying the water to the drill steel is arranged coaxially with the drill steel and the piston, and is held fixed in the anvil block into which the head of the drill steel fits, while the piston slides over the tube and the end of the tube beyond the piston works through packing in a gland. With this construction the water flows through a closed tubular path to the drill steel, and any entrance of air into the tube, or leakage of water therefrom is prevented.

17,723 of 1920 (145,585). W. North, Hanover. Electrostatic precipitation of dust from gases.

20,316 of 1920 (148,388). R. E. Bea, Paris. Electric furnace for obtaining copper and oxide of zinc from old brass.

28,429 of 1920 (167,980). E. Leclercq, Haine St. Paul, Belgium. Improvements in hammer drills, wherein the air-distributing chamber, instead of being arranged at the end of the cylindrical body of the drill and within it, is arranged laterally

of said cylindrical body. The distributing chamber is arranged between the body of the drill and a laterally projecting handle, and is divided by a partition into two compartments, one of which contains an automatic ball-valve mechanism, while the other contains a sliding member, actuated from the outside by means of a pivoted thumb-lever to control the feed of compressed air from the air conduit in the handle.

29,191 of 1920 (168,205). L. F. RICHARD, Edinburgh, and R. G. D. SMALL, London. Improvements in rollers for guiding and supporting haulage cables in mines, etc.

6,783-4 of 1921 (167,725-6). A. H. EUSTIS, Norfolk, Massachusetts. Improvements in the inventor's process for recovering sulphurous acid from furnace gases.

NEW BOOKS, PAMPHLETS, Etc.

☞Copies of the books, etc., mentioned below can be obtained through the Technical Bookshop of *The Mining Magazine*, 724, Salisbury House, London Wall, E.C. 2.

Barium Minerals 1913–1919. Pamphlet, 26 pages. Price 9d. Published by the Imperial Mineral Resources Bureau.

Lead and Zinc Ores in the Carboniferous Rocks of North Wales. By BERNARD SMITH. Paper covers, octavo, 162 pages, illustrated. Price 5s. 6d. net. Vol. XIX of the Special Reports on the Mineral Industry of the United Kingdom, published by the Geological Survey.

Lead, Silver-Lead, and Zinc Ores of Cornwall, Devon, and Somerset. By HENRY DEWEY. Paper covers, octavo, 72 pages, illustrated. Price 2s. 6d. net. Vol. XXI of the Special Reports on the Mineral Industry of the United Kingdom, published by the Geological Survey.

Lead and Zinc Ores of the Lake District. By T. EASTWOOD. Paper covers, octavo, 60 pages, illustrated. Price 2s. net. This is Vol. XXII of the Special Reports on the Mineral Resources of Great Britain prepared by the Geological Survey.

Transvaal Chamber of Mines 31st Annual Report, 1920. Cloth, quarto, 270 pages. Published by the Chamber at Johannesburg, and at the London offices of the Chamber, Salisbury House, E.C. 2.

The Working of Steel; Annealing, Heat-treating, and Hardening of Carbon and Alloy Steel. By F. H. COLVIN and K. A. JUTHE. Cloth, octavo, 250 pages, illustrated. Price 18s. net. New York and London: McGraw-Hill Book Co., Ltd.

COMPANY REPORTS

New Modderfontein Gold.—The report of this company operating one of the two greatest gold mines in the Far East Rand, covering the year ended June 30 last, shows that 1,222,266 tons of ore was raised, and that after the removal of waste 1,083,100 tons, averaging 9·96 dwt. gold per ton, was sent to the mill. The yield by amalgamation was 347,855 oz., and by cyanide 179,622 oz., making a total of 527,477 oz., being 9·74 dwt. per ton. The par value of the gold produced was £2,240,000, or 40s. 11d. per ton, and the amount realized was £2,969,198, or £54s. 10d. per ton. The working cost was £1,270,146, or 23s. 5d. per ton, leaving a working profit of £1,699,051, or 31s. 5d. per ton. The shareholders received £1,400,000, the distribution being at the rate of 100% The yield per ton was about ½ dwt. less than during the previous year. The tonnage milled was 114,000 higher. The working cost per ton was up 1s. 6d. On the other hand, the premium realized on the sale of the gold was much higher than during the previous year, accounting for £751,427 out of the total profit of £1,699,051. The development operations have continued to disclose valuable ore. In particular high-grade ore over a wide stoping width has been found in the area west of No. 2 shaft between the 12th and 13th levels. This is the most important discovery in this section of the mine. The developments in the eastern side of the mine have continued to fulfil expectations. The total ore developed throughout the mine during the year was 1,234,100 tons, averaging 10·5 dwt. per ton. The reserve is estimated at 8,884,600 tons, averaging 8·4 dwt. per ton, figures much the same as those of the previous year. It will be observed that the grade of the ore treated continues to approximate more closely to the ore developed than to the average grade of the reserves.

Modderfontein East.—This company belongs to the Central Mining-Rand Mines group, and was formed in 1917 to acquire a new lease area in the Far East Rand and to amalgamate this with the properties of the Cloverfield and Rand Klip companies. Development is proceeding from No. 1 shaft in the Cloverfield area and from Nos. 2 and 3 shafts in the leased areas. The report for the year ended June 30 last shows that 20,270 ft. of development was done, of which 15,934 ft. was on the reef. Of the reef sampled 51% proved payable, and the reef disclosure was 8,130 ft., 25 in. wide, averaging 15·8 dwt. per ton. The best ore has been found round No. 1 shaft, that at Nos. 2 and 3 being of medium grade. The total ore reserve is estimated at 1,611,700 tons, averaging 7·7 dwt. over 57 in. During the year 296,987 tons of ore was raised, and this, together with 91,928 tons from the dumps, was sent to the sorting stations, when 23% was sorted out as waste. The amount sent to the mill was 299,800 tons, averaging 9·04 dwt. per ton. The yield of gold by amalgamation was 57,397 oz., and by cyanide 61,541 oz., making a total of 118,938 oz. The revenue from the sale of the gold was £662,699, or 44s. 6d. per ton, and the working cost £452,910, or 30s. 5d. per ton, leaving a working profit of £209,789, or 14s. 1d. per ton. The expenditure on capital account during the year was £379,579, of which development represented £110,480, and plant most of the remainder. New shares were issued, bringing in £317,136. The ore is still being shipped for treatment to the Apex plant, which is held on lease. The plant of the Simmer Deep and Jupiter companies has been purchased, but its erection on the spot is deferred until financial conditions improve.

Nourse Mines.—This company belongs to the Central Mining-Rand Mines group, and operates a gold mining property in the central part of the Rand. The report for the year ended June 30 last shows that 560,009 tons was raised, and after the removal of 9% waste, 508,350 tons averaging 6·58 oz. per ton was sent to the mill. The yield of gold by amalgamation was 103,155 oz., and by cyanide 57,344 oz., making a total of 160,499 oz. The sale of the gold realized £903,318, of which

£28,915 accrued from premium. The working cost was £284,970, leaving a working profit of £18,837. The revenue per ton milled was 35s. 6d., the cost 30s. 10d., and the profit 4s. 8d. Of the revenue per ton 9s. represented premium. It will be seen that but for the premium, a considerable loss would have been incurred. The ore reserve has been maintained, and stands at 1,589,030 tons, averaging 6·9 dwt. per ton.

Consolidated Main Reef.—This company was formed in 1896 as a consolidation of other companies that had operated in the middle west Rand since 1888 and 1893 respectively. On the death of Sir S. Neumann the control was taken over four years ago by the Central Mining and Investment Corporation. In 1918 the adjoining Main Reef West property was absorbed. The report for the year ended June 30 last shows that 634,705 tons of ore was raised, and after the removal of 11% waste, 561,800 tons, averaging 7·39 dwt. gold per ton, was sent to the mill. The yield by amalgamation was 144,250 oz., and by cyanide 52,454 oz., making a total of 196,704 oz. The gold realized £1,105,077, of which £282,724 accrued from premium. The working cost was £905,952, leaving a working profit of £199,124. The revenue per ton milled was 39s. 4d., the working cost 32s. 3d., and the working profit 7s. 1d. Shareholders received £155,950, the dividends amounting to 12½%. It will be seen that if it had not been for the gold premium the year's working would have resulted in a loss. As compared with the previous year, the yield per ton was about 0·7 dwt. less, while the cost went up 3s. 1d. As regards ore reserves these are calculated at 1,176,500, averaging 7·5 dwt. per ton, as against 1,186,000 tons averaging 7·6 dwt. Development during the year maintained the total reserve, but it is stated that this was in the nature of selective development in the most promising part of the mine, and that in other parts it will be necessary to press development without delay. If no large amounts of ore are found in other parts within the next year or so it is feared that the scale of extraction will have to be reduced.

Transvaal and Rhodesian Estates.—This company was formed in 1911, and conducts a land and mining business in various parts of South Africa. The chief mining interest is the Fred gold mine in the Filabusi district of Rhodesia. The report now issued covers the year 1920. During this time 18,950 tons of ore was milled at the Fred mine for a yield of 13,971 oz., being an extraction of 14·75 dwt. per ton. The working profit not allowing for depreciation was £29,324. The reserve at the end of December was 48,350 tons, averaging 16·2 dwt. per ton. The accounts of the company show a balance of profit of £22,402, which is carried forward.

Mount Morgan.—The report of this Queensland gold-copper mine for the half-year ended May 31 shows that operations were continued until the Easter holidays, March 24, after which the low price of copper made it inadvisable to resume operations. During the period of activity 87,719 tons of ore was raised, of which 26,852 tons was smelting ore and 60,712 tons concentrating ore. At the concentrating plant 60,907 tons averaging 1·95% copper and 6·1 dwt. gold per ton was treated, the products being as follow: 8,303 tons of jig concentrates averaging 1·93% copper and 6·65 dwt. gold, 8,205 tons of table concentrates averaging 3·61% copper and 13·1 dwt. gold, and 4,089 tons of flotation concentrates averaging 15·8% copper and 28·25 dwt. gold. At the smelter 50,108 tons of material was treated, yielding 1,697 tons of copper and 23,777 oz. of gold. This material consisted of 30,537 tons of ore, which yielded 2·43% copper and 7·35 dwt. gold per ton, 7,837 tons of jig concentrate, 9,563 tons of sintered table and flotation concentrates, and 2,118 tons of Many Peaks ore. On May 31 the reserve of ore was estimated at 3,257,287 tons, averaging 2·57% copper and 6·04 dwt. gold per ton. The accounts showed an income of £372,571 and a net profit of £13,884 for the half-year

Anantapur Gold Field.—This company was formed in 1906 by John Taylor & Sons to acquire old workings in the Anantapur district, Madras Presidency, South India. Parts of this property have been worked by subsidiary companies, the North Anantapur Gold Mines, Ltd., and the Jibutil (Anantapur) Gold Mines, Ltd., shares in which are still held by the present company. The report for the year ended March 31 last shows that dividends, interest, etc., brought an income of £2,395, against an expenditure of £973. At the North Anantapur exploration is being done on the 950 ft. level south of No. 5 shaft, but so far with no result, while at the Jibutil development is in hand for exploring the lode at and below the 500 ft. level from No. 1 Prospect shaft. Nothing is being done on the company's own sections of the goldfield. The directors are considering the acquisition of shares in a gold-mining syndicate about to be formed to test other properties, on which a favourable preliminary report has been received.

Arizona Copper.—The report of this Edinburgh company operating at Clifton, Arizona, for the year ended September 30, 1920, shows that 1,046,331 tons of ore was raised, coming from the individual mines as follows: Humboldt, 739,806 tons; Clay and Petaluna, 180,948 tons; Yavapai, 37,053 tons; Coronado, 51,121 tons; Horse-shoe, 5,941 tons; lease ores, 31,462 tons. Of this amount 1,012,040 tons was concentrating ore averaging 2·08% copper. The concentrate averaged 6·97% copper, and the recovery was 75·5%. The smelter treated 147,206 tons, and the output of copper was 17,846 tons (of 2,000 lb.), of which 13,882 tons was electrolytic and 3,964 tons bessemer. The output was less than normal, owing to curtailment of operations due to the inability of producers to market their copper. The accounts for the period showed a loss of £319,672, but against this was £292,373 excess profit duty refunded and £96,575 reduced provision for United States taxes, so that there was an actual profit of £69,275. The company also issues a report for the eight months ended May 31, 1921, at which date output was suspended owing to the continued fall in demand and price. During this time 573,397 tons of ore was raised, averaging 2·15%, which on concentration yielded material averaging 7·84%, with a recovery of 75·3%. The smelter treated 80,710 tons, and produced 9,275 tons of copper. Experiments on flotation and on the treatment of the ores of lower grade have been continued and many improvements have been introduced or suggested. The accounts for the eight months show a deficiency of £254,277. Reference is made in the Editorial columns to the negotiations for the sale of the company's property to the Phelps-Dodge Corporation.

EDITORIAL

IS it too late to ask the authorities to reconsider their decision to hold the Great Exhibition of 1923 at Wembley Park? Surely this site is not sufficiently accessible. Many potential exhibitors are hesitating for this reason.

DR. J. D. FALCONER, the Director of the Nigerian Geological Survey, is giving a series of lectures on the Wonders of Geology at the Imperial College of Science, South Kensington. Many of our readers will no doubt be glad to know of these lectures, for they fill a gap between a college course and lectures interesting only to specialists. There is no charge for the course.

OWING to an error of transcription the monthly output of Trinidad Leaseholds, Ltd., was given as 15,000 *barrels* instead of *tons*, in the article by Mr. H. B. Milner on the Trinidad oil industry in the October issue, p. 211. As this company is the largest individual producer on the island, this error of units is particularly unfortunate. We hope all who keep the MAGAZINE will make the correction.

THE approaching Conference of the Powers at Washington is of direct interest to mining engineers, as one of the subjects to be discussed is the "open-door" in the development of the world's oilfields. The average Englishman's attitude in this matter is clear. He does not wonder that the British Government and the British and Continental oil companies have felt compelled to protect themselves against the notorious tactics of the Standard Oil Company.

ON the 24th of this month Earl Haig is to unveil the Memorial to the members of the Institution of Mining and Metallurgy who fell in the war. This Memorial has been designed and executed by Colonel P. N. Nissen, whose artistic modelling is already well known among mining men. We postpone a detailed description until after the ceremony of unveiling, but in the meantime it may be mentioned that the sculptures are unconventional, realistic rather than symbolic, and in that way appeal strongly to the emotions of those who know the nature of the work which their dead friends did in the war.

ABSTRACTS of several articles on petroleum appear in our Mining Digest this month. Of these, the description of the Southern Mexican oilfields will be of particular interest to investors and users of petroleum, for it presents the question in a more reassuring manner than many recent articles on the subject. Dr. Hume's historical account of the Egyptian oilfields fills a gap in the general literature of oil technology, for hitherto published information on these oilfields has appeared in official reports issued by the Egyptian Government, which are not easily accessible to the public. A third article, written by Mr. H. W. Hixon, deals with speculations as to the origin of petroleum. Mr. Hixon is a distinguished metallurgist, who is noted for unorthodox and daring views in the domain of economic geology. He takes the side of the inorganic theory of the origin of petroleum, and in this article he gives some of his reasons for adopting this view. He is, of course, in a minority, for perhaps only he and Mr. Eugene Coste argue that all petroleum comes from an inorganic source. Mr. Coste expounded his arguments in a paper read before the Institution of Mining and Metallurgy in October, 1911, so it is not necessary to quote him here. Other oil geologists, while admitting the possibility of forming a series of hydrocarbons from inorganic substances, are disposed to attribute the origin of most of the petroleum so far known to an organic source, particularly from the animal kingdom. They rely largely on the analogy between oil and coal, and nobody doubts the vegetable origin of coal. There is one point in Mr. Hixon's argument which we do not follow. He says that an oil containing no oxygen cannot come from an organic source, and that neither could an oil which is poisonous to life. In reply, we would say that oils are obtained containing no oxygen and poisonous to life by the distillation of coal, which is admittedly of vegetable organic origin, so no reason can be given for supposing that hydrocarbons cannot be obtained from an animal organic origin by means of some heat treatment. Though the inorganic origin of petroleum has few supporters among geologists the theory is sound enough in itself, and it only suffers owing to the presence of one more obvious. Arguments in favour of the inorganic theory are always welcome in these pages.

The Russo-Asiatic Negotiations

As has been recorded already in these pages, Mr. Leslie Urquhart and his co-directors of the Russo-Asiatic Consolidated, which owns by right the Kyshtim, Tanalyk, Ridder, and Ekibastus mining properties in the old Russian Empire, have been in negotiation during most of the current year with the Soviet Government or its emissaries, with a view to obtaining a return of the concessions and permission to recommence operations. Mr. Urquhart was in communication with the Soviet emissary in London, M. Krassin, for several months, and after full discussion and reference to headquarters in Moscow a tentative agreement was reached. The position was so favourable that Mr. Urquhart left for Moscow on August 14. From the time of his arrival, August 20, to September 12 he was continuously engaged in discussing the proposed contract with the Technical Economic Commission, which was appointed by the Soviet Government for this specific purpose. This Commission was a large one, and included many men who were of commercial and professional standing before the revolution. The Commission had only advisory duties, for the decision on each point was really vested in three High Commissioners, Ministers of the Soviet Government, who, in turn, had to submit the draft contract to the final decision of the Council of the People's Commissaries, under the presidency of M. Lenin. The draft contract contained twenty-seven clauses, of which eighteen were agreed by both parties. The remaining nine, as drawn up by the Soviet Government, could not possibly be accepted by Mr. Urquhart, and any suggestion or expostulation on his part was ineffective in securing a satisfactory modification. He returned to London, and, after discussion with his co-directors, placed his views and experiences before M. Krassin. Subsequently he addressed a letter to M. Krassin, putting on record an account of the stumbling-blocks in the way of agreement with the Soviet Government. This letter has been circulated widely among shareholders in the Russo-Asiatic Consolidated, and among the public generally. It gives not only the details of these particular negotiations, but it reflects by means of this specific case the actual attitude and ideas of the party at present in control in Russia and Siberia.

Space forbids us giving anything like full quotations from this letter, but one or two points may be mentioned. For instance, the royalties to be paid on sales of products were outrageously high, not only sufficient to wipe out any possible profit, but to cause serious continuous losses to the company. Then, again, the Government refused to forgo their absolute control of labour, both skilled and unskilled, Russian or foreign, and asserted their right to labour or military conscription, irrespective of the regular occupations of the workmen and staff. Under such a regime any local organization of the Soviet Government could take a Russian employee, a professional man or a highly skilled workman, away from his job, and set him to clean the streets.

The crucial test of the value of the contract arose during the discussion of the arbitration clause. At first sight, the proposal that all disputes and misunderstandings as to the carrying out of the contract should be referred to a permanent arbitration commission of three, one from each side and one neutral or foreigner, should be acceptable, but Mr. Urquhart soon found from the discussion that such a Commission would be ineffective, because the so-called State recognizes no contract between individuals. Communism does not recognize the right to private property on which the previous civil and criminal code was based, so magistrates have been suppressed and courts of justice have been abolished. Nothing has been substituted for these, except a "Court of Revolutionary Conscience." Under the new system taxes have been abolished, as have all laws and regulations relating to mining, factories, customs, forestry, and railways, and their place has been taken by incomplete decrees and instructions issued from day to day. Furthermore, the communistic system does not recognize any obligations between individuals; thus no contract between two persons can be enforced. Nor does the State itself recognize obligation on its part towards individuals or subjects; on the other hand, everybody is in absolute subjection to the State. Thus it is obvious that the Arbitration Commission would have virtually no status. The position of a neutral or foreigner on the Commission would be impossible, for the Soviet Government, even if it consented to his presence, would hardly bow to his advice. As for referring disputes to the Court of Revolutionary Conscience, this could not be accepted by

Mr. Urquhart, for the members of that court are admittedly communists, and are of none too high intelligence, and are lacking in legal training. Obviously their judgments would always be prejudiced against capital.

In his letter to M. Krassin Mr. Urquhart also makes reference to the increasing powers of the Secret Police, otherwise the Che-ka, or Extraordinary Commission for Combating Counter Revolutions. This organization was originally started for the purpose of enforcing the communistic system on the unwilling people, but it subsequently developed into a sort of predatory body, accuser, judge, jury, and executioner all in one, with absolute power of life and death, responsible only to M. Lenin and the communistic leaders. The Soviet Government itself is at the mercy of this body, and any of its decrees may be rendered ineffective by Che-ka, if the communistic controllers think fit.

Altogether the position in Russia is such that no commercial undertaking has a ghost of a chance of success, and the hopes entertained by Mr. Urquhart of re-establishing his mining enterprises by the aid of the Soviet Government have been rudely dashed. How Russia is to be saved and the control of the country placed in better hands is at present an insoluble problem.

Ventilation and Efficiency

In the current issue we publish the first half of an article by Mr. Bernard W. Holman, Lecturer in Mining at the Royal School of Mines, on "Ventilation and Working Efficiency." During the last few years the scientific aspect of working conditions in respect of dry and cool air has received considerable attention in this country, more particularly in the workshops and factories, and also more recently in the coal mines. But among metal miners the subject has not been widely studied on the same lines. The credit for the introduction of these scientific investigations at gold mines is due to Messrs. Orenstein and Ireland, who have conducted many experiments on the Rand. Perhaps it would be more correct to say that they were the first to give the public the benefits of their results, for it is probable that the studies were started at an earlier date by the engineers of the St. John del Rey Company. In the latter case, however, very little has been published. In a paper read early this year before the Institution of Mining and Metallurgy on the new shaft at the City Deep, Mr. E. H. Clifford discussed the question in detail, and whetted the appetite of English mining engineers for more on the same subject and for an exposition of the underlying principles, starting as it were from the beginning. Many members of the Institution appeared to have forgotten that an article on the subject by Mr. David Penman had appeared in the MAGAZINE for June, 1920. This article still holds good as a general introduction to the subject. It was felt, however, that further discussion of the principles was desirable, and readers will therefore be glad to have Mr. Holman's critical paper on the scientific questions involved. A great deal of literature has appeared in this and other countries, usually written by medical men and seldom by mining engineers. Their books, reports, pamphlets, and articles are scattered, and are not easily traced or obtained, and when they have been secured the metal-mining engineer finds considerable trouble in picking out his requirements from among the vast multitude of records and arguments. Readers of the MAGAZINE will therefore be greatly indebted to Mr. Holman for presenting the questions in logically consecutive order and for unravelling so many complicated and often contradictory views and arguments. In the second section of his article there will be included a bibliography that will indicate the lines on which further and special study may be pursued.

This subject is still further impressed on the mining engineer by the paper, read at the meeting of the Institution of Mining and Metallurgy held on October 27, by Dr. Leonard Hill, the pioneer of the study of the science of ventilation and the inventor of the kata-thermometer, a small instrument somewhat like a clinical thermometer, intended for the purpose of estimating the comparative rapidity of the cooling effect of air on the human body. Those who attended the meeting had the additional privilege of hearing some interesting remarks by Dr. J. S. Haldane, another great authority on atmospheric conditions as affecting efficiency of work. Dr. Hill and Dr. Haldane differ considerably in some of their views, or at least in their method of applying and emphasizing details. Dr. Hill is a believer in sunlight and fresh air, as well as in the prevention of an undue increase in body temperature. On the other hand, he has shown that low oxygen content of the air and high carbonic acid content are not necessarily

inimical to health. Dr. Haldane adduces evidence that the average coal miner is as healthy as the average agricultural labourer, and argues accordingly that comparative darkness and impure and dusty atmosphere are not necessarily harmful to the health and strength of the worker. He agrees with Dr. Hill on the question as to low oxygen content and high carbonic acid content in the atmosphere, but he also deprecates the objection to smoky and dusty atmospheres, arguing that the human system can easily adapt itself to variations in the composition of the atmosphere, and that dust and microbes give the phagocytes of the lungs excellent occupation and training. Dr. Haldane and Dr. Hill were agreed, however, on the main theme of the latter's paper, that is to say, the body temperature must never be allowed to rise unduly under any circumstances, though it is only recently that Dr. Haldane has agreed with Dr. Hill that air in motion rather than dry and cool air has the desired effect of lowering the body temperature.

The subject of ventilation and working efficiency, as discussed by Mr. Holman and Dr. Hill, is only one of the phases of the study of the human body in relation to ventilation and work. The presence of poisonous gases such as carbonic oxide, and of deleterious dust which overcomes the phagocytes, are equally important subjects of discussion; and if no reference is found to them in the papers mentioned it must be remembered that it is best to discuss one thing at a time.

Shetland Copper

In several issues recently we have made reference to the venture undertaken for the purpose of working the deposits of copper ore at Sand Lodge, near the southern end of the Mainland of the Shetland Isles. In the September issue an outline was given of the history of these workings extending over a century, and it was then shown that in spite of many efforts no satisfactory outputs had ever been obtained. Of the earlier operations there are only the barest records, and details as to the nature of the work done are not now available. It was not until the reopening of the mines in 1872 by Mr. John Walker that any reports were published. From that date to 1879, when the property was sold to the Sumburgh Mining Co., Ltd., a number of engineers examined the property, and their reports were sufficiently favourable to warrant the flotation of this company. Yet in 1881 we find the resident manager referring to the impossibility of making a profit on inferior ores with insufficient appliances, and urging that the shaft should be sunk deeper in order to find richer ore. The company did not raise the £5,000 which he recommended for the purpose of buying additional plant and sinking deeper, and the operations accordingly lapsed. The mines have been examined since then on more than one occasion, and various proposals for reopening have been made. The reports, however, were generally adverse, and nothing was done until 1920. It is interesting in this connexion to record that during the war the mines were suggested as a possible source of copper, but knowing their history the authorities at the Ministry of Munitions did not think it worth while even to examine the deposits.

As we have said, work at the mines was once more started in 1920. This was undertaken by the Shetland Exploration Syndicate, Ltd., which in August of this year transferred the properties to another company, the Sand Lodge Mine, Ltd. The reports on which the company was floated and the operations undertaken were made by Dr. J. B. Garbe. After the shafts had been unwatered and a fair amount of machinery bought, the directors heard something of the history of the mines, and considered it advisable before they went any further to have a second opinion on the properties. Mr. H. H. Yuill, M.Sc., M.Inst.M.M., a partner in the firm of Bainbridge, Seymour & Co., Ltd., was accordingly asked to make an examination He, with his assistants, made a study of the geology of the district and of the ore deposit, and systematically sampled the lodes. The result of his investigations was so unfavourable that work was immediately suspended and the project abandoned. His view, expressed in a few words, was that "there is no ore carrying payable values in copper in the Sand Lodge mine, and no mineral occurrences exposed in the underground workings or on the surface which indicate that payable ore would be disclosed by exploration work."

To give an idea of Mr. Yuill's reasons for coming to this conclusion, we give herewith a summary of his general statement. There are two parallel lodes, about 120 ft. apart, known as the West and East lode respectively. The West lode is from 7 to 12 ft. wide, and has been worked along the strike by open-

on, and by two inclined shafts sunk to a depth of 140 ft. At various times between 1798 and 1880 a total of about 10,000 tons of lode material has been extracted and sold as iron ore. A much smaller amount of copper ore and regulus was shipped. The lode material down to the 66 ft. level consists of spongy iron oxides, hematite or limonite, with nests of malachite in vugs. Below this level, the lode material gradually changes, until at 96 ft. it becomes crystalline siderite, associated with calcite and dolomite, and containing disseminated iron pyrites with some copper pyrites. The sampling of accessible portions of the stopes and drives gave an average copper content of 1·17% over a width of 80 inches. There is no workable tonnage of this ore developed and opened-up for stoping. The East lode has been developed by a vertical shaft and levels have been opened at 230 ft. and 275 ft. Drives extend along the lode in both directions on the 230 ft. level for a combined length of 380 ft. Of this length 80 ft. at the south end carries only traces of copper. Of the remaining 300 ft. the sampling gave 1·21% copper over an average width of 114 inches. There are no blocks of ore developed and ready for stoping on this lode.

As regards the character of the ore, it may be said that the ore extracted from the West lode was entirely iron ore, and that the copper content was always small. On the other hand, the East lode contains much sulphide. Iron pyrites is disseminated fairly regularly through the siderite, but the chalcopyrite occurs irregularly, sometimes on the walls of the lode and sometimes within the lode.

Mr. Yuill's report contrasts very strongly with those written by Dr. J. B. Garbe. Writing on April 4, Dr. Garbe mentions veins of rich copper ore varying in width from 15 to 24 inches, and carrying over 20% of copper, and veins of from 6 to 10 ft. of mixed ore averaging from 3 to 8% of copper. He also states that practically every foot of the development over 1,400 ft. at the 240 ft. and 300 ft. levels shows payable copper ore. He considers that the West and East lodes join at a point between the 240 ft and 300 ft. levels from the vertical shaft. On the other hand, Mr. Yuill's interpretation of the geology is to the effect that these are two parallel lodes and that there is no junction in depth. In estimating the ore reserves, Dr. Garbe takes a measurement for 500 ft. along the strike and the depths on the dip between the surface and the presumed junction of the lodes, reckoning the width of the East lode at 6 ft. and that of the West lode at 14 ft., and calculates that there is 369,000 tons of ore in sight, fully developed and ready for immediate mining.

The engineers who reported in 1879 appear to have made an assumption on somewhat similar grounds, though the general tone of their reports was not quite so favourable as those of Dr. Garbe. Dr. Garbe also says that the " mine is fully proved and developed, and is ready for stoping, with an immediate production of 1,000 tons of ore per week ; a production of 500 tons per week could be proceeded with almost at once, and 1,000 tons as soon as the equipment now being erected and prepared is completed."

The treatment of the ore is by no means simple. Chalcopyrite is not of much higher specific gravity than siderite, so that water-concentration would not be easy. Moreover, with so much pyrite in the ore, a concentrate high in copper cannot be obtained. It is doubtful whether the Minerals Separation, Ltd., would care for the ore. An alkaline circuit would be necessary, and the low grade of the ore and its limited extent would not appeal to their engineers. Dr. Garbe recommends roasting, leaching, and electrolytic treatment, but his statement is sketchy and lacking in detail. Moreover, it is to be questioned whether ore containing so much carbonate and oxide attackable by acid can be profitably treated by acid-leaching.

It is always a thankless task for a mining engineer to write a condemnatory report on a property, and much more so when previous reports made by other parties have been favourable. It is also unpleasant for a technical journal to join in a discussion of the situation which so arises. We should not have referred to the subject but for the fact that preliminary notices foreshadowing a public issue of shares had made their appearance in the financial Press. The directors now recognize that their first expert adviser was mistaken, to begin with, in his interpretation of the reports of the 'seventies, and that after the workings were unwatered he allowed his enthusiasm to get the better of his judgment when examining the pyritic siderite. The directors immediately abandoned the idea of appealing to the public for working capital, and they and their friends have footed the bill for the expenditure incurred.

REVIEW OF MINING

Introduction.—Though business throughout the country remains depressed, signs of improved conditions are being seen here and there. The Government has at last become aware of the fact that the extravagance of the spending departments is leading the country into debt, and that excessive taxation is killing enterprise. The cost of living and the level of wages are gradually falling. The prices of coal and iron are relaxing somewhat. The only unpleasant factor of the situation is the continued inability of the coal miners to grasp the position. They still seem to consider themselves privileged persons, outside the influence of economic laws.

Transvaal.—The Government has now taken a hand in trying to solve the labour question at the mines, and both General Smuts and Mr. Malan, Minister of Mines, have discussed the matter with the Miners' Union. The prospects of a recovery in dollar exchange and the concurrent disappearance of the gold premium is the cause of the Government taking this step. Certain proposals, details of which are not yet to hand, were put before the Union, intended for the purpose of increasing the amount of work done by the natives. As these were taken to represent the thin end of the wedge in the matter of removing the colour bar, and the consequent diminution in the white force, the Unions was dead against them, and the secretary said that if the proposals were persisted in the whole of the white miners in South Africa would strike within 48 hours.

Of the quarterly reports issued by Rand mining companies covering the period to the end of September, perhaps those of New Modderfontein and City Deep are the most interesting. As compared with the previous quarter, the cost per ton milled at New Modderfontein was 1s. 7d. less, and of 3,830 ft. of new development on the reef 2,750 ft. was payable, averaging 37·4 dwt. over 19 inches. At City Deep 1,080 ft. of new development on the Leader averaged 28·5 dwt. over 25·9 inches. The profit for the quarter was £210,994, which constitutes a record for this company.

Some months ago we mentioned that Cornish miners now out of work did not care to go to the Rand. One reason for not wanting to go there arises out of the present Phthisis law, which provides that applicants for work must satisfy the Medical Bureau that they are not suffering from any disease of the respiratory organs. It is clear that a Cornish miner is not inclined to travel to Johannesburg for medical examination, for, if rejected, he would have to bear the expense of a futile double journey. The Minister of Mines has now decided to allow a preliminary examination in England, but as the result of such examination is not to be considered final, the position is not greatly relieved. Obviously some further concession will have to be made if Cornish miners are to be attracted to the Rand.

South-West Africa.—The outputs of the Otavi mines at Tsumeb are being reported once more. During the six months to the end of September the shipments were 19,000 tons of ore, 830 tons of copper matte, and 150 tons of metallic lead.

Rhodesia.—The output of gold in Southern Rhodesia during September was returned at 52,436 oz., as compared with 53,200 oz. in August and 45,471 oz. in September, 1920. Other outputs for the month were: Silver, 12,977 oz.; coal, 54,504 tons; copper, 262 tons; asbestos, 588 tons; arsenic, 18 tons; mica, 4 tons. No diamonds or chrome ore were reported.

The Gold Fields Rhodesian Development Co. has made a profit of £114,064 for the year ended May 31 last, and has distributed £125,710, the dividend being at the rate of 10%. Under present conditions this result is distinctly satisfactory. The company's principal mining interests are in the Shamva, Falcon, Asp, and Planet-Arcturus gold mines, and in the Rhodesian and General Asbestos, Rhodesian King Asbestos, and the Standard Arsenic properties.

The Cam & Motor Mining Company has issued cable reports relating to rich discoveries on the 11th level. For 135 ft. on the south drift the average assay-value was 210s. over 55 inches, or, omitting the rich patches, 50s. over the same average width. It will be remembered that this company recently resumed operations after a spell of development and a rearrangement of treatment plant. The returns for September show 13,900 tons of ore treated for a yield of 4,771 oz. of gold. The par value of the gold is given at £20,233, and the premium obtainable is estimated at £5,500.

The working cost, including development redemption, was £10,241, and the royalties absorbed £1,286, leaving a profit of £2,260. It will be seen that the profit was about equal to the premium.

It will be remembered that the Jumbo company acquired a new property a year or more ago, known as the Tip Top. Milling commenced in January of this year, and until June 30, the date of the end of the company's financial year, 7,489 tons of ore was treated, yielding 2,628 oz. of gold, which sold for £13,801, including premium. The directors report that the working cost is less than expected, and that development results warrant further sinking. The company has obtained options on the Defiance claims to the west, and prospecting is now in hand.

Nigeria.—The position of the tin-mining industry continues to be very unfavourable and concentrates are accumulating in many quarters. For instance, the Keffi Consolidated reports that it has 200 tons of concentrates on hand in Nigeria. The question is often discussed by the various companies whether it would not be politic to curtail the output substantially.

With regard to gold mining in Nigeria, to which reference was made last month, the Naraguta company has issued an official statement announcing the early departure of Mr. Clyde Allan to Nigeria, where he will develop the gold lodes recently discovered at Birnin Gwari. At this juncture it is of interest to quote from Mr. Allan's report written in April last. The prospecting was originally commenced on alluvial ground, and by systematic loaming a lode was discovered. This, however, proved to be too low in content to warrant prospecting. Further work to the north was rewarded by better results. Good loams were got about ¼ mile to the north and a costeen at a depth of 6 ft. below the surface disclosed some good grade ore. A shaft, known as the A shaft, was sunk to 50 ft. to water level, and a cross-cut east cut the shoot, which had dipped out of the shaft at 35 ft. This cross-cut proved the ore-body at this point to be 12 ft. wide and ranging in value from 3 dwt. to 10 oz. per ton, the values being much higher than near the surface. An attempt was made to sink A shaft below water, but at 60 ft., or 12 ft. below water level, the water became too strong for the windlass to cope with it. A sample obtained at this depth showed 30 dwt. values; the corresponding section of the lode at 50 ft. assayed 14 dwt. Although the rich shoot at water level is not very long, there is evidence that it will lengthen as it goes down. The ore-body has no defined walls. It has been traced by loaming for a distance of 3 miles. The installation of a pump is necessary to prove the lode below water level. The crushing plant, to which reference was made last month, consists of a three-stamp mill.

Mr. Clyde Allan's discoveries have served to draw attention to the auriferous belts of Kano, Birnin Gwari, Ilorin, and other places in Nigeria, and we understand that several prospecting parties are being organized by other companies, in particular by companies hitherto associated with Australian mining. The fact that Mr. Allan conducted his prospecting for lodes by "loaming" shows that he is an Australian mining engineer.

Australia.—Labour still blocks the way to a resumption of operations at Mount Morgan. Last month the directors applied to the Arbitration Court for a new scale of wages 20% lower than those now ruling. The Court granted this application, subject to a small government subsidy for the men. The local branch of the Australian Workers' Union has, however, refused to allow the men to resume work on these reduced wages.

The ore reserves at the Kalgurli mine being exhausted, the assets are being realized, and notice has been given for the liquidation of the company. The surface plant is being bought by Oroya Links for £20,000. This latter company has very large reserves of ore that are unpayable with its present plant, but it is calculated that, by working on a larger and more effective scale by the addition of the Kalgurli plant, satisfactory profits can be made.

We hear with regret of the final closing of the Mount Boppy mine, the chief gold producer in New South Wales, and situated not far from the Great Cobar copper mine, now also closed. The mine was acquired by Messrs. John Taylor & Sons, who floated a company to work it in 1899. The total gold output has been £1,812,699, and the dividends £446,058. Operations have been impeded from time to time during recent years alternately by floods and prolonged droughts. Finally the developments ceased to disclose ore either longitudinally, laterally, or in depth. During the past year the mine was kept going by selective mining of the reserves. The payable portions are now exhausted, and operations have ceased. The company owns half a million tons of

sand and slime residues, and these are to be worked on royalty terms conjointly with a local company. The directors are in negotiation for the acquirement of another property, which is sufficiently near to warrant the transference of the plant and machinery. As the examination of the property is not yet concluded, nor are the terms of purchase settled, no details are as yet available for publication.

It has been decided that some of the accumulated zinc concentrates purchased by the British Government under that unfortunate ten-years' contract are to be shipped to England, and offered for sale here through the British Metal Corporation. It is believed that the Government will be prepared to take any price within reason, so that the public expenditure may be recouped to some extent, and also that the zinc smelters shall be able to operate at a profit and provide work for the men at present unemployed. The zinc mine owners in Great Britain view this policy with unabated dismay, but are hoping that the Government will be able to do something which will bring employment to the home zinc miners.

Amalgamated Zinc (De Bavay's) reports by cable that, during the half year ended June 30, 128,646 tons of zinc material was treated for a production of 37,201 tons of zinc concentrates and 815 tons of lead concentrates. The accounts did not show any substantial profit, but the directors have decided to distribute a dividend of 1s. per 20s. share out of the equalization reserve.

In a recent issue it was announced that the Mount Bischoff tin mines in Tasmania had been closed, though no definite reason was assigned in the cable message. By mail we learn that the stoppage was caused by exceptionally severe snowstorms which continued for over a week. Open-cut working and transport were rendered impossible, the roof of the new mill buildings gave way, and the electric light and power cables were broken. It is feared that many prospectors in this region will have lost their lives from exposure, and there is also some anxiety as to the fate of the osmiridium washers.

Reports have been received in this country of an oil enterprise on the Fitzgerald River, near Bremer Bay, West Australia. There appears to have been considerable excitement locally, and Government geologists were sent to examine. Competent mining men, however, declined to believe in the discovery, even in spite of the alleged samples. It was ultimately found to be a case of salting of a particularly clumsy character.

India.—Shares in a new company called the Anglo-Burma Oil Co., Ltd., have been offered to the public this month. The company is to acquire the shares of the New Indian Petroleum Co., Ltd., which controls certain oil-mining rights at Singu, Burma; it acquires also some oil lands in Trinidad. In both cases the properties appear to be only unproved prospects. The financial arrangements are complicated, and the method of issuing the shares is not an attractive one.

A company called the United Steel Corporation of India, Ltd., has been formed in India by Bird & Co., of Calcutta, in association with Cammell, Laird & Co., of Sheffield. The company will take over collieries and coalfields in Bihar and Orissa, controlled by Bird & Co., and will develop iron ore deposits. Works are to be built with a capacity of 600,000 tons of pig iron per year, and steel works and rolling mills are to be erected.

Malaya. — It will be remembered that eighteen months ago the Ipoh Tin Dredging Company issued further capital for the purpose of extending operations and constructing two new dredges. Unfortunately the slump in tin and the impossibility of selling the whole of the new shares have placed the company in a position of financial difficulty, and the company has been unable to complete payment for the dredges. The company has this month made an agreement with F.M.S. Timah, Ltd., which controls the neighbouring Kamunting Tin Dredging Co., whereby the latter will acquire one of the new dredges and the land which it is intended to work.

Siam.—The Renong Tin Dredging Company made only a small profit, £4,028, for the year ended June 30 last, just sufficient to pay the dividend on the preference shares. The output of the two dredges at Renong was 756 tons, as compared with 433 tons the year before, but any benefit derivable from this big increase was nullified by the drop in the price of tin. There was also additional expenditure on a dam built for the purpose of diverting the river channel so as to enable one of the dredges to work the upper portion of the valley. The third dredge has been removed to the Rasa property, in the State of Selangor, acquired early last year. It started operations on March 17, and until June 30 had extracted 90¼ tons of concentrate

[illegible], which corresponds to a yield of [illegible] per yard.

Cornwall.—The directors of East Pool & Agar have approved the plans of the engineers for the sinking of the new shaft, and arrangements are already in hand for a commencement of operations. This work will relieve the position as regards unemployment in Cornwall to a certain extent, and the fact that no tin will be produced for some time is all to the benefit of the tin market. The decision to start the shaft apparently indicates that the proposals to join forces with South Crofty have ended in nothing.

The last meeting of the Levant Mining Co., the old cost-book company, was held last month, when the final disposition of the funds was arranged. The property now belongs to the new company, the Levant Tin Mines, Ltd., formed in February of last year. When the new company was formed the intention was for Geevor Tin Mines, Ltd., to provide working capital so that Levant and Geevor could be worked conjointly. Owing to the slump in tin, Geevor has not been able to provide the funds, so Levant continues independently, under the direction of Colonel F. F. Oats. He has bought the stamp-mill from Tincroft, and will start working ores accumulated at the surface during long years. With the income thus derived he intends continuing development between the 120 and 170 fm. levels.

The plight of Cornish mining was the subject of a question in Parliament last month, put by Sir Edward Nicholl. The Minister of Mines was not sympathetic at the time, but it is understood that he has sent representatives to Cornwall to investigate. There have been plenty of investigations, committees, and reports already, but nothing has come of them, and the only recommendation likely to be made by the present investigators, namely, an amalgamation of the mines, is not likely to be acceptable locally.

North Wales.—The Aber-Llyn company, which was formed to work a zinc-lead mine near Bettws-y-Coed, has now given up all hope of working this property at a profit under present conditions. The company also tried a china-clay property in Brittany, but soon found out that there was not sufficient material of satisfactory grade. Attention is now being turned to two groups of old gold mines, in Rhodesia and Portuguese Zambesia respectively. The former are the Killarney and Hibernia mines, and the latter are known as the Machinga and Mudzi River properties. Mr. Stephen J. Lett is to go out to make investigations.

Canada.—A cable has been received to the effect that violent rainfall (or cloud burst) has devastated the coastal region north of Vancouver. Several towns were overwhelmed by torrents of water, and in particular Britannia Beach suffered in tragic manner, fully fifty houses being carried away and many people drowned. The concentrating plant of the Britannia Mining and Smelting Company, which owns the big low-grade copper mine behind, was built at Britannia Beach, but it was burnt down in March last. Details are awaited by mail of this further disaster.

United States.—The recent policy among the American oil magnates of squeezing down production by lowering the prices to an unnaturally low level has had serious effects on the Anglo-United Oilfields, Ltd. This company was formed in 1919 to acquire oil lands in the Dallas field, Wyoming, and its development work and its contracts for the sale of its oil appeared to be perfectly satisfactory. New shares were created a year ago for the extension of the scale of operations. The depression of the price for the crude oil to the ridiculous figure of 28½ cents per barrel made it quite impossible for the company to meet expenses, let alone make a profit. At this juncture the underwriter of the new shares failed to carry out his contract, and about the same time also certain creditors who had advanced money for the purchase of the pipe-line pressed for repayment. In order to save the company it has become necessary to reconstruct and raise further funds. The price obtainable for crude oil has recently recovered, and Mr. Campbell M. Hunter, the company's technical adviser, is of opinion that operating expenses can now be met.

Bolivia.—Last month we quoted the financial results of the Compagnie Aramayo de Mines en Bolivie for the year 1920. The chairman, in his speech at the meeting of shareholders, held at the new headquarters, Geneva, reported that during the year 2,011 tons of tin concentrate was produced and 973,038 oz. of silver. There was no production of wolfram concentrate, and as usual no figures were given for the output of bismuth. He also mentioned that at the Chorolque mine, which was previously reported to be nearing exhaustion, new orebodies have been found.

VENTILATION AND WORKING EFFICIENCY

By BERNARD W. HOLMAN, O.B.E., A.R.S.M., Assoc.Inst.M.M., F.C.S.
Lecturer in Mining, Royal School of Mines

The author discusses the modern principles of ventilation and working conditions as applied to deep and hot mines.

The Human Machine.—In the case of a miner working underground what the employer pays for chiefly is work done. In the simplest case, that of a miner hewing coal in a colliery, or drilling holes in rock by hand in a metal mine, this work done is chiefly mechanical work. It is mechanical work which, actually, a machine could do and which can be measured as foot-pounds as the result of energy expended. Moreover, the miner's body in performing the work under such circumstances expends a given amount of chemical energy by converting it into heat and kinetic (motion) energy, just as a steam plant or an oil engine does when it performs work, although in the case of the human being the change is more truly a biochemic thermogenesis, that is, it does not conform to the Carnot cycle.

In a cool mine, as the efficiency of the human body is good, its employment in place of machinery, where either is applicable, is determined chiefly by the usual factors of first cost (housing and supply), cost of fuel and lubricants (food and drink), running costs (wages), and reliability (health conditions and strike frequency). But in deep and hot mines the question of actual efficiency becomes of paramount importance, because, like, say, a gas engine, the human body will only work between certain temperatures.

As water-jacketing is not practicable in the case of the miner, we have to confine our attention to air cooling. Air cooling can only be external, and the air must be used at low velocities because of the question of comfort; therefore, it can be seen at once that the upper temperature limit for efficient work must be very low. Unfortunately, this upper temperature limit is still further reduced by the complex method of burning (oxidizing) its fuel (tissues) employed by the human body.

Instead of completely burning a single portion of fuel at a time, as does an oil engine, the body partially oxidizes minute portions of a large number of tissues at the same time by means of the well-known reversible reaction: Haemoglobin + Oxygen $\leftrightarrows$ Oxyhaemoglobin.

Under the conditions of concentration and colloid solution existing in the human body, this reaction cannot take place above 130° F., else cessation (death from heart stroke) occurs.

Moreover, the mechanism for the change of heat into work is controlled by reactions in the brain (causing nervous stimulus of the respiratory centre) instead of by a metal governor. These reactions are still more subject to derangement by temperature rise (nervous fatigue, and, at higher temperatures, fever and delirium) than are those in the blood.

Hence it comes about that accurate temperature control of the body itself is absolutely essential for work even at normal temperatures. Nature has provided for this by the provision of an elaborate system of glands for secreting on the surface of the body moisture which, on evaporation, produces a very considerable cooling effect owing to the high latent heat of vaporization of moisture. Without evaporation but little cooling effect is produced by perspiration.

The warmer the surrounding air the more of this water must be produced and evaporated in order to maintain the body at a working temperature by perspiration, and the more rapidly must the blood be pumped to the cooled surface of the body. Hence the warmer the atmosphere the greater is the quantity of work done in merely keeping the body cool. Other secondary causes increase this additional work even more, although, of course, conduction and radiation also play their part in the cooling of the body.

Still saturated air at the same temperature as the body produces no cooling effect whatever, but still dry air, owing to the motion of the body in work, might produce an adequate cooling effect by evaporation alone, because naturally the dry air could take up moisture and thereby cause evaporation of the perspiration. Thus it is seen why such great importance is attached to the humidity of the air in a working place, sometimes rather to the neglect of other factors.

On the other hand, moving saturated air, so long as it was at a lower temperature than the body, would produce a cooling effect by

conduction, and, if a sufficient quantity passed over the body, an adequate cooling effect would be produced with saturated air by conduction alone. Hence the importance of the velocity of an air current as well as its humidity when considering its cooling effect. This has no direct connexion with the velocity necessary to supply an adequate quantity of fresh air for breathing purposes. Of course, within limits, the lower the temperature the greater the cooling effect for a given velocity, particularly if the air is not saturated. The effect of velocity in accelerating evaporation is then of prime importance. In fact, in practice both velocity and low humidity are employed wherever possible.

In the study of hygienic ventilation, of the three factors, humidity, velocity, and temperature, most attention was devoted to humidity, but in metal mine ventilation, where the laying of dust may necessitate a humid atmosphere, increasing attention is now being devoted to the effects of velocity and temperature on the actual rate of cooling of the body surface and to determine what conditions of humidity and velocity will give a healthy atmosphere even when the temperature is high.

The application of these results in practice is complicated by the fact that although two men may be equally cooled their capacity for work is not the same. In a hot healthy atmosphere the sweat glands of one man may act almost automatically and his heart do comparatively little extra work in stimulating increased subcutaneous circulation of the blood, while, under the same conditions, another man may feel so exhausted that he cannot work at all. Such a mathematically difficult matter as a stone or two of fat on an individual would quite invalidate any *a priori* calculations as to his thermodynamic efficiency on a given load. Hence it is readily seen that it is exceedingly difficult to calculate or measure the actual amount of work done in cooling the body under different conditions, although the nett output of work can, of course, be observed.

THE ERGOMETER.—Of late years attention has been directed especially to the actual task of devising means of measuring the output of mechanical work of different individuals as compared with their fuel consumption. For measuring such output of mechanical work various forms of specially adapted dynamometers have been devised, called "Ergometers," but for measuring the corresponding fuel consumption no cheap and handy apparatus has yet been evolved. The simple method of subtracting the unconsumed fuel rejected by the system from the food taken into it gives no useful result owing to the long and indeterminate time factor involved in the building up and oxidizing of individual tissues. Efficiency determinations on this basis would have to be of several days' duration; this and the difficulty of allowing for periods of sleep render the method scientifically and commercially useless in mining practice.

Another simple method is to burn in a bomb calorimeter a proportional part of the day's rations of a number of men, and to calculate the B.T.U. supplied and compare the result with, for instance, the number of inches drilled by hand in a day on the mine by the men who ate the food. Such results are too approximate to apply to the testing of individuals, and are, therefore, more of a check on the food than on the work.

The only method of estimating individual fuel consumption that has met with general success is based on the measurement of the amount of CO_2 expired by such an apparatus as is shown in Fig. 1, for example. Like flue-gas analysis its results are more relative than absolute. Also for accurate work apparatus which is neither simple, cheap, nor easy to manipulate has to be employed to determine the total amounts of gases involved in an experiment. Now that results of definite value have been obtained a simplification and cheapening of the apparatus is to be hoped for. A considerable advance in the ease and accuracy of determinations has been achieved by Professor Langlois for the French Department of War, but no cheapening.

With the human machine the amount of fuel burnt cannot be calculated directly from the amount of CO_2 produced, because other fuels besides carbon are consumed. A factor called the R.Q. (Respiratory Quotient), the ratio by volume of the oxygen consumed to the CO_2 exhaled, has to be used. The reason for this is that not one but three kinds of fuel are oxidized simultaneously in the human machine, namely carbohydrates, fats, and proteins. Each of these takes a different proportion of oxygen for its combustion.

For all carbohydrates the R.Q. is 1, according to the equation :—

$$C_6H_{12}O_6 + 6O_2 = 6CO_2 + 6H_2O$$

That is to say, when carbohydrates are

burnt the volume of carbon dioxide produced is identical with the volume of oxygen consumed.

For proteins and fats the R.Q. is naturally not so high, because part of the hydrogen in these compounds is available for fuel, and therefore uses up oxygen in forming water. Professor Krogh gives the average R.Q. for protein as 0·80, and for human fat as 0·71. The composition of the latter is taken as 76·5% carbon, 12% hydrogen, and 11·5% oxygen.

Alcohol contains still more available hydrogen than fat, and, therefore, has a still lower R.Q., namely 0·66, according to the equation :—

$$C_2H_5OH + 3O_2 = 2CO_2 + 3H_2O$$

If it were not for the unpleasant results of drinking strong beer (as one's sole food) and its only partial assimilation, perhaps only due to lack of sufficient practice, it would be the most efficient of all foods for the miner. Bacon and ham have excellent food values ; also pigs have a more efficient basal metabolism than men, and can feed on the waste products from the manufacture of beer. Therefore, as a mining engineer, one is tempted to desire a thermo-dynamic miner-beer-pig cycle more efficient than any Diesel-Still engine. Unfortunately, one's digestion will not stand it, and in our greatest mining country prohibition would not allow it.

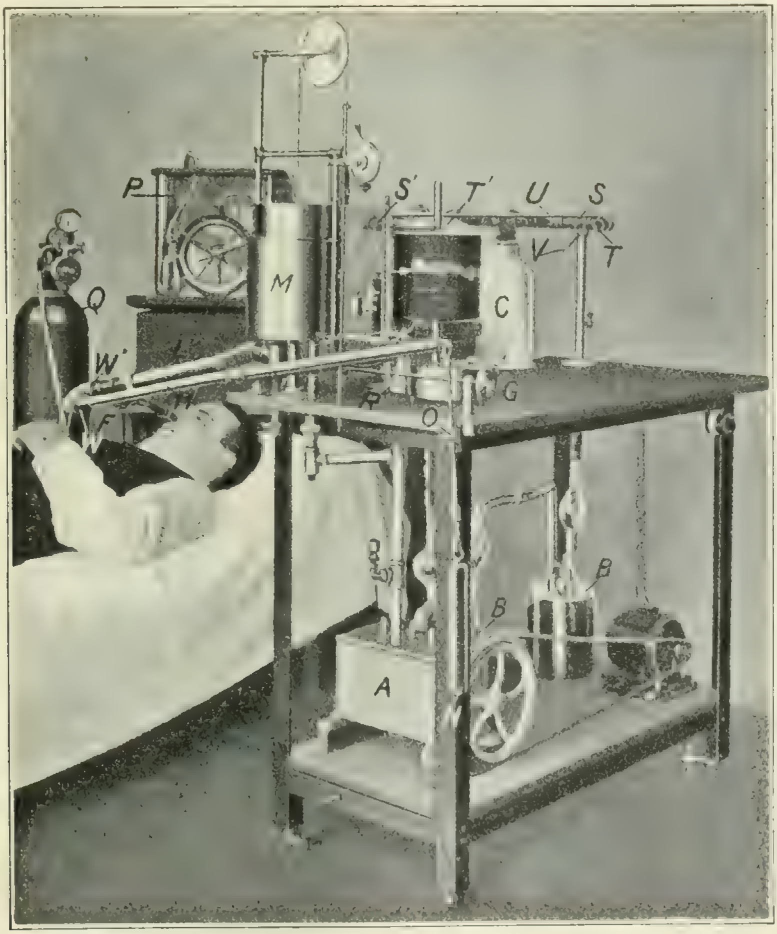

Fig. 1.—Benedict's Respiration Apparatus.

The figures given above are for normal temperatures. The R.Q. rises with increasing temperature and also varies with the load (amount of work done). The following table shows clearly how the R.Q. affects the calculation of the heat produced and the food consumed. The Respiratory Quotient is,

of volumes, is also equal to the ratio of the weight of oxygen consumed to the weight of carbon dioxide exhaled.

Per Litre of Oxygen.

R.Q.	Glycogen Catabolized, grammes.	Fat Catabolized, grammes.	Heat Produced, calories.
0·71	0·0000	0·5027	4·795
0·75	0·1543	0·4384	4·829
0·80	0·3650	0·3507	4·875
0·85	0·5756	0·2630	4·921
0·90	0·7861	0·1753	4·967
0·95	0·9966	0·0877	5·012
1·00	1·2071	0·0000	5·058

The following figures are also useful in such calculations :—

1 litre of oxygen at normal temperature and pressure (N.T.P.) weighs 1·429 grammes.

1 litre of carbon dioxide at N.T.P. weighs 1·965 grammes.

1 litre of nitrogen at N.T.P. weighs 1·255 grammes.

1 litre is equal to 0·0353 cubic feet.

1 cubic foot is equal to 28·32 litres.

1 ounce = 28·35 grammes. 1 gramme = 0·035 oz.

From the above it appears that if fat only were consumed and 45 litres per hour of carbon dioxide were produced, a loss of 32 grammes ($1\frac{1}{8}$ oz.) of fat per hour would result, and a heat production of above five calories per minute might be expected. This would be equivalent theoretically to $\frac{1}{5}$ horse-power.

Dr. Leonard Hill mentions as large an amount of oxygen used per minute as 3·361 litres when bathing in rough cold sea. Taking this as approximately equivalent to 3 litres per minute at N.T.P., with an R.Q. of 0·80, from the above table the heat produced would be 14·6 calories or 0·58 h.p. With 33% efficiency (see later) this would equal about $\frac{1}{5}$ h.p. actually exerted in mechanical effort. This is interestingly near to the old figure of five men to one horse-power. The weight of carbohydrate consumed per hour would be 66 grammes and of fat 63 grammes, a total loss of weight of over $\frac{1}{4}$ lb. per hour. So high a figure would only apply to periods of exertion and would be far less with the same individual sleeping. For the resting body the functional activities amount to only 25% of the standard metabolism (Krogh) ; but a man in perfect training may for short periods of great exertion have a respiratory metabolism twenty times the minimum (Krogh).

In Great Britain many measurements of the output of work have been made for the Mine Rescue Apparatus Research Committee. In these the "Cycle Ergometer" of Professor Martin, F.R.S., was used (Fig. 2). It is fully described in an appendix to their Second Report. It consists of a cycle frame and seat mounted on a stand with a heavy fly-wheel substituted for the back wheel of the bicycle. Round the fly-wheel passes a brake strap, the ends of which are connected to spring balances in the ordinary way so as to constitute a dynamometer brake.

Mr. H. F. Bulman recommends a gear of $3\frac{1}{4}$ to 1 with a fly-wheel 2 ft. in diameter, so that fifty revolutions a minute of the pedals is equivalent to 3,500 ft.-lb., when the difference of tension on the springs is 4 lb. With a dry belt various ranges of load can be obtained by slacking or tightening the belt. The oxygen consumed may be measured through a valve if compressed oxygen is being used on the tests, while the expired air is collected in a bellows-shaped bag of convenient form and supplied with a suitable tube, mouthpiece, and nose clip.

Two other forms of ergometer have been devised and used by Dr. A. J. Orenstein, and were fully described by him in his recent paper (March) before the Chemical, Metallurgical, and Mining Society of South Africa. One of these is a hand-operated dynamometer brake which was calibrated "by substituting a narrow wooden pulley for the driving crank, and of the same radius, and driving the machine by pulling a cord off this driving pulley, the pull being read on a spring balance." This machine, which Dr. Orenstein calls his "rotary dynamometer" (Fig. 3), is very simple to construct and use, but as it is operated by the hand and not by the feet it is not easy to carry out respiration tests simultaneously. Like the Martin ergometer it measures work of a purely unskilled nature and does not imitate closely any operation carried out in mining.

To meet this objection, Dr. Orenstein designed his cylinder dynamometer which actually registers the number and force of the hammer blows given to a piece of drill steel bearing on a diaphragm in a closed cylinder containing boiled water (Fig. 4). The variations in pressure in the cylinder are recorded on an indicator diagram by an ordinary indicator as used in steam-engine practice.

This machine has to be of very robust construction, which gives it excessive weight.

It was also found to be particularly liable to various errors due to " condition of jointing rings, slight obstructions in connecting pipe, presence of small bubbles of air, friction in the indicator piston, etc." This made frequent calibration necessary, and often caused the loss of a day's work. Nevertheless, many successful tests were carried out, the results of which are given in the exceedingly useful paper mentioned above.

capacity to withstand fatigue, vary greatly in different individuals, and, what is of first-rate practical importance, show up in tests of this nature. Hence these tests give us an insight into the nature and effects of fatigue which are shown to be very similar to those of overload on an oil-engine. A fairly heavy task may be performed for a short time without causing any fatigue, but if it be carried on too long a definite state of exhaustion

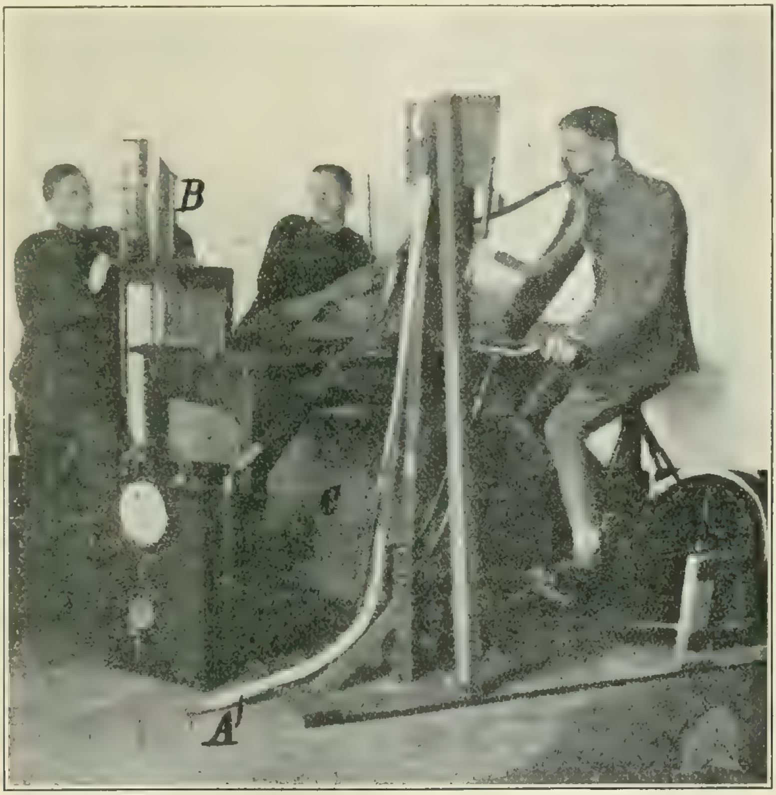

FIG. 2. MARTIN'S CYCLE ERGOMETER.

occurs, and exertion has to be stopped until cooling and re-cleaning has taken place. As is well known a heavy task which would utterly exhaust one man is easily performed by another who has practised it often. This is one cause of the varying results obtained by independent workers, but on the same man the improvement due to training can be definitely measured. Therefore, having found a man to be of good stamina and in good training, one can proceed to test the effect of physical conditions such as humidity and velocity of air on his working efficiency.

EFFICIENCY AND THE INDIVIDUAL.—One of the most striking things about the great mass of work performed on this subject of the efficiency of the human machine is the very different results obtained by different observers. The results recorded (Krogh) by admittedly first-class observers using normal subjects vary from 2·8 cc. of oxygen absorbed per kilogram minute (0·8 calories) to 5·5 cc. of oxygen absorbed per kilogram minute (1·6 calories), but these results have often been obtained by experiments on abnormal subjects, for instance, very ancient paupers.

Briefly, the degree of training, or capacity for exertion, and the amount of stamina, or

EFFICIENCY AND PHYSICAL CONDITIONS.—Adequate oxygen and absence of poisonous

[illegible] necessities for efficient work, and are readily tested for by chemical means, but fatigue and correct body temperature are less readily estimated. The amount of work which produces fatigue is generally left to individual judgment, tempered by a general bonus on extra footage or tonnage (unless the Unions decree otherwise), but correct body temperature is a matter of racial peculiarity tempered by ventilation. There is a fifth physical condition necessary for maximum efficiency, and that is optimum effort. The optimum effort is not necessarily the greatest individual exertion, but is the best distributed effort throughout the shift which will produce the maximum output without producing fatigue. This can only be determined by actual tests. The quantitative study of this question as applied to metal mining is in progress ; for instance, a study is being made of the effect of short and long rests, frequent and infrequent, for hand-drillers.

Optimum effort, like fatigue and correct temperature, depends greatly on the purity, dryness, and velocity of the air, in which the individuals work ; hence it comes about that ventilation is now required not only to supply oxygen and to sweep out noxious gases, but also to cool the workers in the manner which causes their work to produce least fatigue in them. (See tests on optimum speed of walking, p. 17 of the second report on Mine Rescue Apparatus.) Hence the humidity and velocity of the current receive as much attention now in some mines as its quantity and purity, when considering the question of whether or not the ventilation is adequate.

ADEQUATE VENTILATION.—The chemical theory was the earliest accepted explanation of the injurious effects of inadequate ventilation. It was based on the idea that " the evil smell of unclean and badly ventilated places was evidence of a ' vitiated effluvia ' or volatile poison added to the atmosphere by exhaled or expired air," and also that the oxygen content of the air became unduly diminished.

As exhaled air contains much carbon dioxide, the excess of CO_2 found in a badly ventilated place was taken to be a reliable indication of the amount of this poison present. Several Acts and Regulations based on this idea allowed an excess of CO_2 only a few parts per 10,000. Many hygienists supposed CO_2 itself to be a poison, particularly as a large excess of it, such as found in some natural caverns, will cause death. That this latter was a popular delusion was demonstrated long ago by the simple experiment of breathing without any ill effects air with 1% of pure CO_2 added to it. Any sincere investigator can satisfy himself that this is so in the congenial environment of a brewery, where the air often contains over 1% of CO_2. One per cent is, of course, many times the amount (4-10,000ths) fixed as the safe limit in some Acts. Even 3% can be breathed without any ill effect being noticed until muscular exertion is attempted. Then panting ensues, merely owing to the need for greater pulmonary ventilation with such air. Moreover, in man the blood keeps the pulmonary air constant at about 5% CO_2. Hence carbonic acid obviously cannot be a poison, and, of itself, cannot be a cause of the ill effects of bad ventilation.

It was also considered that air in poorly ventilated places became badly impoverished in oxygen, and that this impoverishment caused harmful physiological effects. That this impoverishment is great was directly disproved by analysis.

The diminution of oxygen in ill-ventilated places is exceedingly small, even in a bad stope or in the most crowded room ; it is seldom more than one per cent. Such a small reduction has no harmful effect. This is obvious when one considers that people live comfortably at altitudes where the amount (weight) of oxygen per cubic foot is only two-thirds of that which it is at sea-level. With such reductions of oxygen the pulmonary ventilation and the circulation are increased, the blood is thinner, and the proportion of acids to bases in the blood is altered to compensate for the lactic acid formed. Hence diminution of oxygen cannot be a cause of the ill effects of bad ventilation. This was very clearly demonstrated in one of Dr. Leonard Hill's experiments, where students were confined in an atmosphere of only 17% oxygen, so low that a match would not burn in it. No discomfort was felt so long as the air was kept moving by a fan, and the cooling of their bodies thus assured.

The main part of the chemical theory, the popular idea that exhaled air and stagnant perspiration contain a poison apart from infection, is very severely dealt with by Dr. Leonard Hill. He quotes the work of many experimenters to disprove it, and concludes by saying " there is no evidence worth anything at all as to the existence of

this poison." Certainly too many of these experiments seem to have been tried on animals. Even the Kenotoxin of Weichart was not tried on his neighbour.

Dr. Hill's own experiments on the effects of prolonged breathing of exhaled air were tried on guinea-pigs. Yet guinea-pigs are so different from human beings in their requirements that they can tolerate an extremely high saturation of CO, and in his experiments on them at the bottom of deep boxes they seemed to tolerate all the other conditions of bad ventilation, too.

As water infected with dead bacteria produces so many unpleasant effects it is not quite clear why air so infected should produce absolutely none at all. Shivering and headache are common symptoms of bad ventilation, and also accompany the injection of dead bacteria. Moreover, the quantities of substances required to produce biological effects are so very small that they might easily escape chemical analysis; for instance, one part of copper in 77 million of water is toxic to spirogyra in one minute.

Early medical writers who knew few theories, but had ample acquaintance with facts, believed that the "invariable result of the accumulation of breath and perspiration of human beings crowded together and neglecting personal cleanliness was to produce plague and fever." This seems a safer guide to practice than the idea that the cause of such ill effects are microbes which come from somewhere else, whether from

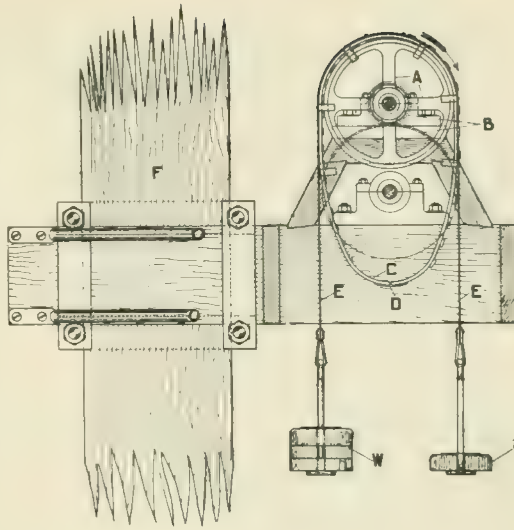

FIG. 3.—ORENSTEIN'S ROTARY ERGOMETER.

colloid solutions or from the survival of the fittest is not explained. One rather wonders whether a visit to a dead end in some metal mine where hand-drilling is being employed on a handsome bonus system, and the booster fan has temporarily broken down, would overpower one not used to such pungent "non-existence." The cause of the physical nausea produced in the visitor, if it is not chemical, might be radio-active; it certainly is not psychic. The remaining alternative is that it is physical. This is precisely the idea which now holds the field as the explanation

FIG. 4.—ORENSTEIN'S CYLINDER ERGOMETER.

of all the effects of bad ventilation, although the bacteriological effect of exhaled air is still adhered to by some. The chemical theory, so far as it concerns the poisonous nature of pure carbon dioxide, and so far as it concerns the harmful effect of any practicable diminution of oxygen, has been completely disproved, and it has been realized that the proper control of the body temperature is the important thing. Hence any definition of adequate ventilation which is based solely on percentages of carbon dioxide and oxygen in the air is not adequate and may be very misleading.

HUMIDITY THEORY. This idea of the physical nature of ventilation has been developed along two lines. Firstly, by those who considered the drying power (humidity) of the air as of most importance in cooling the body by promoting free perspiration, etc.; and secondly, by those who placed their faith more in the free circulation of the air, even though it was not very dry or very pure. The latter method is of most interest to metal miners, because they so often have to deal with saturated air (for dust) underground, and do not need large volumes except such as are adequate for cooling.

The use of hygrometers and anemometers and the application of the knowledge gained thereby to the ventilation of mines is being investigated very fully by the Committee on the Control of Atmospheric Conditions in Hot and Deep Mines, under Professor Sir John Cadman. This Committee has published three reports. (See Bibliography.) Dr. J. S. Haldane had also directed much work on these lines at the Doncaster Coal Owners' laboratory and elsewhere.

As has been pointed out already, proper sweating is a very effective method of cooling the body, because it makes full use of the latent heat of evaporation of the water. So long as the sweat can be produced and evaporated, the less saturated with moisture (lower in relative humidity) the air is at a given temperature, the less volume is required for a given amount of cooling. Therefore, for a given velocity and temperature the lower the humidity is the greater will be the cooling power of the ventilating current. It is for this reason that such great attention has been paid to the question of humidity in colliery practice. In British colliery practice for several generations ample ventilation has been necessary in order to sweep out from the workings all noxious and explosive gases. Hence the quantity, purity, and velocity of ventilating currents has received much study in England. Not only so, but owing to the very high geothermic gradient in this country (over 1°F. for every 70 ft., instead of for every 254 ft. as on the Rand) the question of the cooling capacity of ventilating currents also came early to the fore. There are now collieries working in England at a depth of 3,500 ft. where the rock temperature is about 100° F., a temperature which would not be reached on the Rand until a depth of nearly 9,000 ft. Thus it comes about that the study of artificial ventilation in mines has been left almost entirely to colliery engineers until quite recent years. It is only during the last ten years that artificial ventilation for metal mines was introduced at all generally in South Africa, and then it was chiefly in response to legislation. Natural ventilation had been found adequate for depths of over 2,000 ft. even where very many natives were employed. It may almost be said that it is only during the last five years that *copious artificial ventilation has become a necessity in many metal mines.* In such cases the chief object of artificial ventilation is generally to improve the physical comfort of the men, and is not the maintenance of the purity of the air. As huge volumes of air are not necessary for sweeping out natural gases from such mines, the obtaining of the optimum combination of humidity, velocity, and temperature is a matter of considerable importance. Theoretically each of these three factors can be varied independently to obtain a given cooling power, but unfortunately in many deep metal mines precautions have to be taken against dust. For this latter purpose the crude but safe expedient of spraying the workings liberally with water is generally adopted. This limits the metal mine in such cases to the use of air of nearly maximum humidity, while the colliery engineer is free to base his calculations on the dryness at surface of the air and to take precautions to prevent the unnecessary absorption of moisture by his ventilating current. It is owing to these facts that the wet and dry bulb thermometer has been employed so much by colliery engineers, to the exclusion of other methods of measuring cooling power, while the metal miner resorts to other means. For example, in Mr. Clifford's classical paper before the Institution of Mining and Metallurgy

(February, 1921), any full discussion of hygrometer and anemometer readings, together with all talk of grains of moisture per cubic foot of air and of moisture content charts are absent. The great accumulation of recorded practical experience and sound experiment by colliery engineers was of little value to him as far as it concerned the cooling power of ventilating currents. Nevertheless, the principles underlying the use of the hygrometer should be understood by all.

In the first report of the Committee on Hot and Deep Mines, the use of the wet and dry bulb thermometer as a hygrometer is very clearly explained as follows :—

The use of the wet and dry bulb thermometer rests on the fact that when there is a sufficient air-current to swamp the influence of radiation and conduction . . . a moist surface will assume . . . " a definite temperature between the air temperature and the dew point."[1] " When no other source of heat or cold is affecting the surface this intermediate temperature is known as the 'wet bulb' temperature, and is the temperature assumed by the bulb of a thermometer kept moist with water.' It is the minimum temperature to which a moist surface can be cooled by the air present at the given velocity.

The skin temperature of a perspiring man always lies between the body temperature and this "wet bulb" temperature. As long as a man is perspiring normally his skin temperature will approximate to the wet bulb temperature more closely the higher the velocity of the ventilating current. Increase of velocity, therefore, increases the cooling effect on the skin, but increase of humidity, shown by approximation of the wet bulb temperature to the dry bulb temperature, considerably reduces it until, when the air is saturated, one has to rely on velocity and difference of temperature alone for cooling power.

In still air Dr. Haldane found that 88° F. during rest and 78° during work with minimum clothing were the highest wet bulb temperatures a miner could stand in Cornwall without profuse sweating. (This was independent of separate observations of air temperature, absolute humidity, dew point, and velocity.) In *perfectly still air* Dr. Haldane found that this wet bulb temperature was all-important, and that even when the air current was too hot and warmed a man instead of cooling him this warming depended on the wet bulb temperature and not on the air temperature. In England the outdoor wet bulb shade temperature reached 70° F., but in moist tropical countries it reached 80° F., but with dry tropical heat it may be below 70°, although the shade temperature is 110° or more. Hence, again, we see the importance of low wet bulb temperature, and why in colliery practice so much attention has been devoted to keeping down the wet bulb temperature; also why the wet bulb temperature has been taken as a standard of comfort while the study of the effects of increasing the velocity of the air current has been neglected. In fact, one report of the Hot and Deep Mines Committee speaks of keeping the air in motion in all working places as " a subsidiary aim." When the metal miner has to deal with a hot deep mine it unfortunately has to be his chief aim.

In colliery practice, then, adequate ventilation can be defined by the precentage of foreign gases allowable in the air and by its wet bulb temperature. It is specially necessary to limit the maximum allowable hydrocarbons because of their explosive nature, and of CO because of its toxic effects, but in hot metal mines where the air is saturated such a definition is insufficient. Nevertheless, in both cases " the problem of underground temperature control seems to resolve itself into one of adequate ventilation."

Effect of Velocity.—How adequate ventilation can be defined independently of observations with a wet bulb thermometer in the case of mines with saturated air has been fully worked out and explained by Dr. Hill in his brilliant work the *Science of Ventilation*. This book (two volumes) is a summary of years of original work by the author and his associates, both on theory and on actual experiments. It leaves out some of the more abstruse theoretical considerations dealt with in the original papers, and evolves clearly the author's theory of the paramount influence of velocity on cooling effect. It also gives details of his final triumph, the production of a cheap and extremely simple instrument, the kata-thermometer, which measures directly the actual cooling power of a ventilating current in terms of calories, or of B.T.U.s,

[1] The temperature at which water begins to condense from air of a given moisture content is called its dew point.

per unit of area exposed. Based on such readings it is possible to give a simple definition of an adequate ventilation current in a manner which admits of fully saturated air or of high wet bulb temperatures quite inadmissible in still air, yet makes accurate allowance for the compensating effect of the velocity of the air.

This mode of definition rests on the theory that heat stagnation of the body is the prime cause of the discomforts (headache, sickness, faintness, etc.) resulting from bad ventilation and that movement of air is the surest preventive of such stagnation. Many experiments in support of this theory are given by Dr. Leonard Hill's report on "Ventilation and the Effect of Wind" (see Bibliography). One of the most important of these (p. 15) has been often quoted. It has been carried out by eight different investigators (four in England and four in Breslau). Seven or eight students were shut in an air-tight chamber of only three cubic metres capacity for half an hour. In this chamber the air could be moved by fans placed in the roof and the temperature and humidity could be varied as desired. The CO_2 was gradually increased to about 4%, and the oxygen lowered to about 19%, the air failing to support the combustion of a lighted match. The wet bulb temperature rose meanwhile to over 83° F. With the dry bulb it was a degree or two higher. The discomfort was considerable, pulse rate high, faces flushed and moist, but no headaches. Stirring up the same stale air by means of the fans gave immediate relief. The pulse rate was lowered from 97 per minute to 79, though no fresh air from outside was admitted. The air of the chamber breathed by other students outside caused no discomfort, whereas students inside breathing the outside air before the starting of the fan felt no relief. This experiment was a most astonishing refutation of very widely accepted views on ventilation. Such excess of CO_2, diminution of oxygen, and high wet bulb temperature were each supposed to cause the greatest discomfort. So they did until the fans were started up. In every one of the other similar experiments putting on the fans gave great relief. Moisture and warmth chiefly cause the discomfort and incapability for work associated with a so-called "vitiated atmosphere" when the air is still.

The first effect of heat stagnation is a rise of the skin temperature of the individual and an increase of pulse rate. Following this great extra work is thrown on the heart in its endeavour to keep the body cool by pumping as much blood as possible to the surface of the body. This extra amount of work may, of course, be so great as to cause death. American scientists have shown that the velocity of blood-flow in the arm may be increased eight-fold under such conditions, while in cool air it may fall to one-quarter the normal. Hence the great importance of the cooling effect of an air current is apparent, particularly when manual work is being considered and the heart is already working above normal load. Dr. Leonard Hill not only clearly demonstrated this, but he also showed that the ordinary thermometer, either wet or dry, does not show the cooling effect or heat loss, but only its own temperature.

While the thermometer is a static instrument the human body is a dynamic structure continually producing and losing heat. For example, on a calm or on a windy day the wet or dry bulb thermometer readings may be approximately the same. They may be most misleading as to the conduciveness of such conditions to efficient metabolism, and they give no indication of the bracing effects so familiar, for instance, on a breezy day at the seaside. A kata-thermometer, on the other hand, will give quite different readings under such sets of circumstances and will show clearly in which case the cooling power is greater and how great it is. The same applies to two ventilating currents of different humidity and velocity. Similarly in the case of men working in proximity to machinery, wet or dry bulb thermometer readings give no indication of the cooling effect due to the motion of the air around the machines. This may be quite appreciable and its effect is at once shown quantitatively by the kata-thermometer.

As already mentioned other experiments carried out by Dr. Leonard Hill showed that not only is the utility of wet and dry bulb readings often over-estimated, but that the old ideas about excess of CO_2 and deficiency of oxygen can be dismissed. The prime stimulant to bodily metabolism is cool skin temperature which is best obtained by the motion of air of suitable temperature and preferably, though not of necessity, fairly dry.

Evaporation from the respiratory tract also has a considerable cooling effect on the body when the air is dry, but is not, of course, much affected by external motion of the air.

It is also open to argument whether warm air in motion has the same effect on health as cool still air giving the same kata reading. The mysterious secondary effects of warming or cooling the body by radiation instead of by conduction are little understood. Some people certainly seem to derive increased energy from the sunshine without increased food, but sunshine does not concern the average miner, although one has heard of patent foods which claim to almost make the prospector live on sunshine, so small is the amount of the food supposed to be necessary for a meal. Perhaps such foods, together with the stimulus of "the joys of anticipation," turn the prospector into a species of solar heat engine instead! The effects on health of saturated air are merely mentioned to show that adequate ventilation is not nearly such a simple subject as it seems when one reads the works of any of our leading authorities, but not the work of his opponents.

When we come to the question of testing the degree of ventilation according to any predetermined standard of adequate ventilation we are on much firmer ground.

Testing Degree of Ventilation.—Although the chemical theory of ventilation is incorrect in so far as it concerns impoverishment of oxygen and the harmful effects of small excess of CO_2 above the normal amount found in our atmosphere (0·03% or three parts in 10,000), chemical tests are useful to indicate the degree of ventilation, particularly where CO may be generated by the use of large quantities of explosives. Carbon monoxide (white damp) is a very dangerous poison with a cumulative effect; 0·1% will quickly render a man incapable of walking, while 0·04% will produce the same result but more slowly. Chemical tests are still insisted on in many countries and are troublesome on metal mines where no chemist is employed. Carbon monoxide is particularly difficult to determine accurately. Vogel's blood test is often recommended but it is only approximate. It is hardly suitable for use in a mine. It depends on the simple fact that ordinary blood diluted with 200 times its volume of water gives a yellowish red solution which turns pink with CO. Any such pink solution obtained is compared with standard colour solutions made up from the blood of mice poisoned with CO. The colouration of palladium chloride by CO has been suggested, but it it unreliable, as other organic substances give the colours with this salt. The best method is a combination of the palladium chloride and iodine pentoxide methods. This gives accurate results but requires expensive apparatus and considerable analytical skill, and is therefore best not attempted on a small mine.

Carbon dioxide, on the other hand, can be accurately determined fairly readily on a mine. As big a sample as possible should be taken, its temperature and pressure, of course, being noted. Large glass bottles of known volume and a pair of bellows with a sufficient length of rubber tube to reach to the bottom of the bottles may be used. Rubber stoppers are required and particular care must be taken to keep the bottles dry and clean inside. A sample having been taken, a known volume of potassium hydrate solution is suitably introduced and the bottle well shaken, then washed out. The potassium carbonate formed is determined by titration with a standard solution of oxalic acid which shows the amount of free potassium hydrate left. Lime water may be used instead of caustic potash. The calcium carbonate is estimated by titrating back with oxalic acid, using phenol-phthalein as an indicator.

Humidity on a mine is never determined by analytical methods. Advantage is taken of published tables by which the humidity can be calculated from the observed difference in the temperature shown by an ordinary or dry bulb mercury thermometer, and by one whose bulb is surrounded by a piece of cotton or silk material which is kept moist. The dryer the air at a given temperature the more rapidly will moisture evaporate in it, because the greater will be the cooling effect of the air on the wet bulb thermometer. If the air were saturated with moisture there would be no evaporation from the moist material; the wet and dry bulb thermometers would therefore then give the same reading. A pair of thermometers arranged for the convenient taking of such readings is often called an hygrometer, or, more descriptively, "a wet and dry bulb thermometer."

The simplest forms of hygrometer are liable to errors due to the accelerating effect of air currents on evaporation. The best method of ensuring accurate readings is to ensure a rapid circulation of the air about the hygrometer. In practice it is simpler to circulate the instrument. A form of whirling hygrometer (Fig. 5 overleaf) is described thus in the third report of the Committee on Hot and Deep Mines. Two accurate mercury thermometers, from 6 to

6½ in. long, and with narrow long bulbs, are set in a wooden frame. They are fixed in grooves on cork pads with seccotine, and further secured by two metal bars set flush with the face of the frame. For most of the length of the thermometers the groove is cut right through the wood, so that the thermometers can be read by holding them against the light. An oval hole is cut in the frame of the bulb of the dry thermometer. A glass reservoir for water is fixed at the bottom of the frame. Above the neck of the reservoir the frame is cut away round the

Fig. 5.—Whirling Hygrometer.

bulb of the wet thermometer. This bulb is kept moist by a slip of muslin, which dips into the reservoir. At the top of the frame two pieces of metal are let into the side, and where they project at the top they are bored to take a spindle. The spindle and its wooden handle are secured by milled nuts, so that by a movement of the wrist a whirling motion can be given to the frame. The frame is carried in a tin case, which has a lid at itr top. The lid is secured over the spindle with the handle projecting at the side. The length from the spindle to the centre of the bulbs of the thermometers is about 6 in. The hygrometer may be easily whirled at 200 revolutions per minute, and the air then passes over the bulbs at the rate of over 600 ft. per minute. The prismatic type of thermometer has been found easy to read under all conditions, and from 40° to 110° F. has been found the most useful range for underground work. For surface readings thermometers reading to below freezing-point are, of course, necessary.

The above hygrometer is given as a very suitable one for mine work, though many other forms have been used. Some were shown by Dr. Ezer Griffiths at the Royal Society soiree in May this year, but did not appear suitable for mine work.

The method of expressing the results obtained has been the subject of some discussion. For general purposes of checking the ventilation of a mine it has been agreed to use grains of moisture per cubic foot rather than the wet bulb temperature, or grains per lb. for absolute or relative humidity or moisture. But in considering the variations in humidity throughout a mine "grains per cu. ft." is not a sufficient definition, for a given quantity of air naturally varies very greatly in temperature and pressure, and therefore in volume as it passes through a mine. For example, a cubic foot of air in a hot working place may be a very different amount from a cubic foot of air at the intake of the fan at the surface, or it may not be. This will depend on the compensating effects of the temperature and pressure to be considered, that is, on the depth of the mine, on the barometric pressure on the day of observation, and on the surface and underground temperatures, etc. Hence records of humidity as the actual moisture content in grains per foot in different places may, like some pleasures, have the doubtful virtue of reality, but otherwise be very unprofitable.

The following table from Dr. Hill's *Science of Ventilation* (part i, page 98) gives the maximum capacity of air at different temperatures for holding water vapour. It will be noted that this capacity increases rapidly with increase of temperature :—

Temperature of air Degrees F.	Maximum weight of water in grains per cubic foot.
30	1·94
40	2·85
50	4·08
60	5·75
70	7·98
80	10·9
90	14·7
100	19·7

"Relative humidity" is the term given to the ratio of the weight of water vapour contained in a given volume of air to the weight which this same volume would contain when fully saturated at the same temperature. It is expressed as a percentage. From the above table it will be seen that

when the relative humidity is low and the temperature warm the capacity of the air for water is great; therefore if in motion its effect on perspiration is great. It will be found that in all the best work humidity is expressed in grains of moisture per cubic foot reduced to normal temperature and pressure throughout, that is, moisture in a given mass of air, not a given volume, is recorded when results are plotted; thus a chart is obtained which shows the amount of moisture the air takes up in passing from place to place in the mines, and also gives the absolute humidity at any place (Fig. 6).

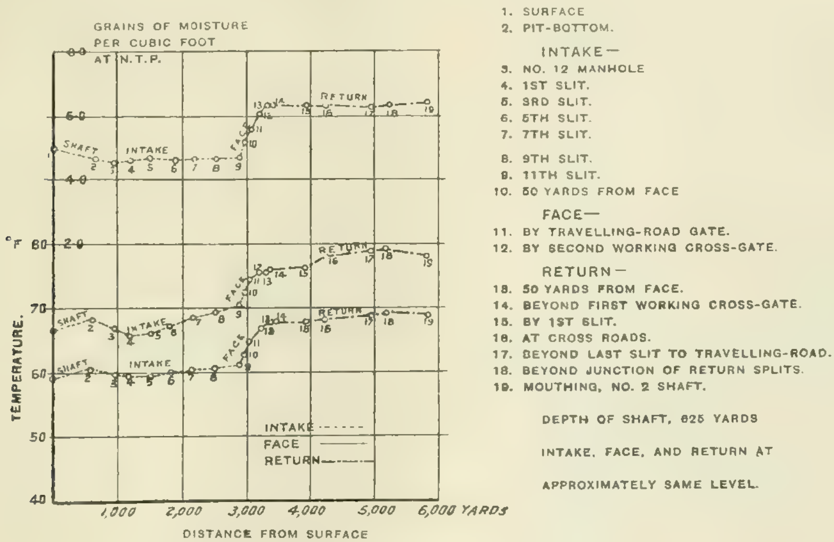

FIG. 6.—CURVES OF HUMIDITY ON A LEVEL

This is a special advantage because absolute humidity has a particular physiological significance. Such a chart combined with a temperature chart will show the loss of cooling power of the air as it travels through the workings provided the air is circulated through them at constant velocity. As this is never possible, and, moreover, as the velocity has such a preponderant influence on cooling power, its variations must be measured and allowed for.

Velocity is generally measured by means of some form of vane-driven anemometer, which has been previously calibrated in air currents of known velocities. These instruments are quite satisfactory for main levels, but give poor results with very low velocities, still worse ones with eddy currents, and none at all with such alternating air currents as traverse the skin of a working miner's body under his shirt or circulate about his bare arms as he works in a dead end where compressed air and not velocity may supply most of the all-important cooling effect. This latter class of case is of much practical importance, and together with the whole question of the effect of clothing can be dealt with but poorly by means of the hydrometer. Moreover, even in simple cases, it is often very difficult, particularly with slow air currents, to calculate the contributory cooling effect of velocity when given it and the hydrometer readings. Some writers appear to have applied the mediaeval principle of circumventing the pure concept. The effects of velocity have been ignored and humidity set up in its place as the all-important factor in cooling effect, although, to quote Mr. H. S. Ireland, " it is almost impossible in connexion with work in mines to overstate the importance of movement in the air."

All temptation for engineers to accept a simple faith in humidity has been taken away by the invention and perfection by Dr. Leonard Hill of that most convenient of instruments, the kata-thermometer. This invention is particularly opportune, coming as it does at the very time when the problem of deep metal mining is forcing itself upon the attention of many engineers.

The kata-thermometer is a special instrument which measures directly the actual combined cooling effect on a surface of an air-current of given velocity, temperature, and humidity; and also gives

the cooling effect due to radiation, convection, and evaporation, without the use of anemometers and wet and dry bulb thermometers or other hygrometers. It not only gives a single correctly integrated and perfectly intelligible figure, but it can be applied to eddy currents, low velocities, and even to still air. It is so compact that it can be readily carried in the pocket and

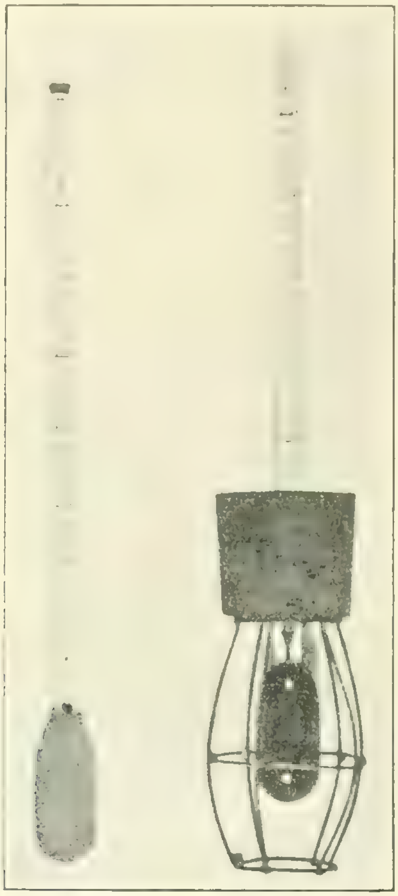

FIG. 7.—KATA-THERMOMETER.

can easily be used for taking observations next the skin underneath a man's clothing. It weighs less and costs less than any reliable anemometer or hygrometer, and, above all, is extremely simple to manipulate and easy to read in a poor light.

Also it is extremely simply constructed in a single piece, with no moving parts to get out of adjustment. In fact, it has been so perfected and so simplified that there almost appears to be nothing in it to write about. A glance at the history of other experimenters' failures and a day or two digesting Dr. Hill's 511 pages of *The Science of Ventilation*, will soon convince the reader of the enormous mass of work which went to produce this triumph of applied theory. The theory itself is given in several papers before the Royal Society (see Bibliography), and is far from simple, so may be omitted here, but a description of the instrument (Fig. 7) is of more general interest.

It consists essentially of a large-bulbed alcohol thermometer designed for the ready measurement of its own rate of cooling from 100° F. to 95° F. This range of temperature is chosen to give a mean of 97·5° F. (36·5° C.), which is approximately that of the clothed body surface. A bulb about 4 cm. in length and 2 cm. in diameter of known area, with a stem 20 cm. long has been found to give a sufficient time-interval for accurate observation so long as the temperature of the air is below 90° F. or over 105° F. The top of the stem terminates in a small reservoir, which gives a margin for overheating the instrument without bursting the bulb and also allows the cooling to settle down to a steady rate before the 100° mark is reached. A thin muslin finger stall is supplied with each instrument so that either dry or ordinary wet kata readings can be taken.

The dry kata reading gives the cooling power by radiation and convection, while the wet kata gives the cooling power by radiation, convection, and evaporation, that is, the total cooling power of the ventilating current. The dry kata reading is sometimes used for quite a different purpose, namely, to measure the velocity of air currents when they are moving very slowly.

(*To be concluded.*)

Commercial Motors.—The fifth International Commercial Motor Exhibition was held at Olympia, London, from October 14 to 22. A large number of motors were on show that are applicable for haulage to and from mines, and there were also many tipping motors that are in demand among mining men. Among the makers may be mentioned the following: The Daimler Company, Ltd., Ransome, Sims, & Jefferies, Ltd., Walker Brothers (Wigan), Ltd., Leyland Motors, Ltd., Fodens, Ltd., Tilling-Stevens Motors, Ltd., The Maudslay Motor Co., Ltd., John I. Thornycroft & Co., Ltd., Karrier Motors, Ltd., The Sentinel Waggon Works, Ltd., and Sheffield Simplex, Ltd.

A HISTORY OF MINING IN CHILE

By F. BENITEZ, A.R.S.M., D.I.C., Assoc.Inst.M.M.

INTRODUCTION.—Mining is intimately connected with the settlement, development, and even with the discovery of all that portion of the American continent colonized by the Spaniards. Unlike that heroic band of Pilgrim Fathers, who sought refuge in New England to escape religious persecutions and to be able to follow in peace the same callings and occupations as of old, the no less heroic Spanish adventurers who came to America did so with the hope of quickly bettering their fortunes in order to return to Spain to lead a life of ease and luxury, or were simply led there by a spirit of adventure. Greater contrast cannot be imagined than that existing between the Spanish Argonauts and the English Puritans. Comparing Pizarro and Cortez, Valdivia and Almagro, Ojeda and Mendez with Brewster, Bradford, Carver, and even Standish, we find nothing in common in both types except the same dauntless energy, grim determination, and finality of purpose. There the resemblance ends. The Spaniards were primarily men of war, soldiers of fortune first and last, seekers after something more solid than all the glory won in France, Italy, and Flanders. The Englishmen, deeply righteous and men of peace, emigrated in search of religious freedom, the thing above all others that they sought. It is well to bring out the great difference between the two types of men who were the progenitors of the two great races of the American continent, because in them we shall find not only the reason of the great contrast which the slow and peaceful settlement and growth of the United States and Canada offer to the imperfect and turbulent development of the Spanish-American republics, but also the key to some of the differences in the psychology of the two races.

The foremost thought of the early Spanish adventurers who came to the New Continent, which they imagined to be India and the islands of Japan, was to become rich quickly in order to return to the Peninsula. The idea of settling in the New World never entered their minds, and as agriculture—the only other possible occupation in a new country—was too slow and unremunerative an undertaking for their adventurous and fickle nature, it is not surprising that the greater number turned to mining as the most rapid means of acquiring wealth. The great quantities of gold, precious stones, and silver which the Incas of Peru had accumulated in their temples and palaces, perhaps through centuries of hard toil, fired their imagination, and a most active and thorough search for the source of the precious metals took place. The story of their adventures makes most wonderful reading, and for a record of mad audacity, unbounded faith, and heroic courage it has no equal in history. On the other hand, the Puritans came to New England accompanied by their wives and families. Their wish was to settle quickly and to form a colony as soon as a suitable site was found. Encumbered as they were by their women folk, they did not travel far, nor did they mix with the native population. The result was that for centuries the English settlers only colonized a long and narrow strip of land along the Atlantic coast from the St. Laurence to the Savannah river, and the rush westward came a long time after and under different conditions. Very different from this was the colonization of Spanish America. Most of the early Spanish soldier-miners who followed Columbus were young and unmarried. Their dominating desire for gold was for ever compelling them to hunt for that mythical El Dorado, the goal of their ambitions, and, as a consequence, in a comparatively short space of time, little more than a century, they had explored the greater part of the American continent, from Northern Mexico to Cape Horn, and from the Atlantic to the Pacific coast. When tired and disappointed in their search, they would rest awhile until the gold fever would take hold of their souls again, and their peregrinations would start once more. We see, as an example, that many of the soldiers who came with Valdivia for the conquest of Chile had served with Cortez in Mexico, under Pizarro in Peru, besides having fought in Central America. The Spaniards married freely Indian women, and the result was a mixed race, Spanish on the father's side, Indian on the mother's. Spanish women did not come to America in large numbers until a great many years after the conquest was ended ; for in those early days ships were scarce and small and the space available was far too valuable to waste on women when men and horses, cattle

and plants were so badly needed to carry to completion the formidable enterprise Spain had so lightly and ignorantly undertaken.

Another important fact must be taken into consideration when finding reasons for the great differences in the development of English and Spanish America. The English colonists, as has already been said, were primarily farmers. Agriculture binds the man who cultivates the soil to his land, and he becomes part and parcel of it. He takes root in his ground, as it were, much as the trees and the corn that he plants do; he learns to love it, and in the end passes it on to his sons, and these, in their turn, to theirs. The United States was first a farming country, then an industrial one, and lastly mining developed. Mining is a permanent industry in a particular place or district while the mines continue to pay. When the deposits are worked out or become impoverished so that they cannot any longer be mined at a profit the population that lived on the mines moves elsewhere and the mining camp becomes deserted. Some of the first Spanish settlements were mining camps. Therefore they were not, they could not, be permanent.

Gold.—The early inhabitants of Chile, or "mapuches," lived in the Stone Age, until conquered by the Incas of Peru at the beginning of the fifteenth century, from whom they learned the art of mining. When the Spaniards Almagro and Valdivia travelled southward from Peru into Chile they did so in the hope of finding great abundance of the precious metals, being misled by the wonderful tales the Peruvian Indians told them about the great wealth of gold Chile contained. They were disappointed in their hopes of finding much gold in Chile, for, as it is well-known, Chile is not rich in the yellow metal. Only placer deposits were exploited in those days, the first being that of Marga-Marga near Valparaiso. This kind of mining increased greatly in the second half of the sixteenth century, and it is calculated that in those fifty years more than 72,000 kilograms of gold were recovered. The system of working the deposits was extremely crude and very cheap, as all the work was done by Indian slaves, who received no payment and only the barest means of subsistence from their masters. The risings of the Araucanian Indians during the whole of the seventeenth century compelled the Spaniards to exchange the pick for the sword, and as a consequence the production of gold decreased to about half that of the previous century. In the eighteenth century there was a renaissance of gold mining in Chile, brought about by the discovery of gold in vein deposits. No extensive goldfield was found, but many rich lodes were worked throughout the whole length of Chile, from Itata to the Atacama desert. The average production of gold is estimated to have reached about 1,000 kilograms per year in the first ninety years of the eighteenth century. This figure rose to 2,000 kilograms per year in the last ten years of the eighteenth and the beginning of the nineteenth century, but this last figure represents the high-water mark in gold production in Chile.

The causes which have contributed to the decadence of gold mining in Chile have been many. Chile, as has already been said, has never been rich in gold, and although its occurrence is widespread throughout the country, the ores are of low grade and the deposits of limited extent. So far no goldfield worthy of the name has been found in Chile. The great impetus which gold mining received under Spanish rule was due primarily to the active search made for the precious metal by the Spaniards to whom all other things were practically of no value. This is proved by the fact that under the Spanish régime more gold was produced than has been recovered since. Free labour in the form of Indian slaves, and the rudimentary and cheap methods of exploitation used were also contributory causes to active production in the early days. Thus the gold-placers and the richest and most accessible vein deposits were worked out first. Later the struggle for independence coupled with the unsettled state of the country caused a reduction in output. Lastly the growth of trade with foreign countries, a direct result of the declaration of independence and free trade, directed the mining activities of the country to copper and the nitrate fields.

Silver.—Although more plentifully found in Chile than gold, the Spaniards gave very little attention to silver, which being devoid of value to them as a medium of exchange was not so necessary to them as gold. Moreover, silver is not found in placer deposits, but in veins, and as vein mining presented to the Spaniards, lacking as they did even the most rudimentary equipment, an undertaking far more difficult of solution than the simple washing of river gravels carrying detrital gold, it is not surprising to find

that silver received no serious attention under Spanish rule. Even supposing that the difficulties of mining the silver ores had been surmounted satisfactorily, the Spaniards would have been faced by a still more unsolvable problem in most of the mines, namely the successful metallurgical separation of the silver from the elements combined with it. The chief silver minerals found in Chile are proustite, pyrargyrite, and cerargyrite, though native silver has been found in great quantities occurring in veins in limestone.

The beginning of the eighteenth century marks the serious commencement of silver mining in Chile, though in those early days a few unimportant deposits were worked in the provinces of Santiago and Aconcagua in Central Chile. Towards the end of the eighteenth century the very important deposits of the department of Copiapó in the province of Atacama began to yield their rich ores, but the great epoch of silver mining in Chile does not correspond to the colonial régime, but coincides with the declaration of independence in the nineteenth century. Many were the rich silver mines discovered in Chile during the nineteenth century. That of Agua Amarga in Vallenar was the first to be worked. Then followed that of Arqueros in Coquimbo, and the famous Chañarcillo and Tres Puntas in the department of Copiapó. Another famous group of mines were those of Huantajaya, near Iquique. Caracoles (1870) was another famous silver district situated in the province of Antofogasta. The Condes mines near Santiago, now worked for copper, yielded considerable quantities of gold and silver from the upper levels. Of these mines the most famous and rich were those of Chañarcillo, which from 1832 to 1859 produced $60,000,000 worth of silver. The Huantajaya mines produced $22,000,000 of silver.

The value of the production has, like that of gold, decreased considerably, and silver mining to-day is only a shadow of what it was, especially in the second half of the nineteenth century, when between 100,000 and 200,000 kilograms of silver were produced annually. In the present century the annual production has never reached more than 70,000 kilograms per year (1900 and 1901). The silver won lately has come from ores other than silver, especially since 1916, when out of 47,500 kilograms only 10,800 were derived from silver mines proper. The following table gives the production for the years 1907 to 1917 inclusive :—

Year	From Silver Mines. Kilograms	From other ores. Kilograms	Total Kilograms
1907	15,542	3,194	18,736
1908	23,926	19,643	43,569
1909	13,511	22,397	35,907
1910	11,964	22,994	34,956
1911	11,122	16,553	27,675
1912	9,760	20,418	30,178
1913	11,744	17,507	29,252
1914	9,847	17,598	27,445
1915	8,712	16,525	25,238
1916	10.780	36,660	47,440
1917	10,533	42,860	53,393

Undoubtedly the chief causes of the decline in the production of silver is due to the exhaustion of the bonanzas found in Northern Chile, from Coquimbo (latitude 30° S.) to Iquique (latitude 20° S.) in the last century, and to the fact that no new deposits of the importance of the old ones have been discovered. In several districts the mines were abandoned on reaching a depth of 500 ft., while in others rich ores have persisted to depths exceeding 1,000 ft. To what extent the mines were abandoned owing to impoverishment in depth, faulty management, or lack of equipment, is a debatable point ; but the probabilities are in favour of the last. To those who are well acquainted with the primeval methods of mine exploitation still in vogue in almost all the Chilean mines, where no modern machinery is used and no systematic exploratory and development work is carried out, it is clear that only the very rich ores would pay to mine in those days. It is the opinion of many mining engineers well acquainted with the country that many of the silver mines now abandoned and full of water would pay good dividends if properly equipped and scientifically exploited. Yet another reason for the decreased production is the antiquated method employed for extracting the silver, namely amalgamation, which only gives a poor recovery. Cyanidation, in spite of its general application elsewhere, has yet to be introduced seriously in Chile. The fall in the price of silver has been also a contributory cause to the decline in silver mining ; for whereas in the second half of the last century, the great epoch of silver mining in Chile, the metal was quoted in London around five shillings per ounce, since 1900 it has stood at about two shillings previous to the recent boom.

Copper.—For much of the information I give here relating to the history of copper

mining in Chile, I am indebted to a most interesting lecture delivered by the Chilean engineer, Don Santiago Marín Vicuña, at the National Library in Santiago dealing with this subject.

According to two old Spanish chroniclers, Mariño de Lobera and Garcilaso de la Vega, copper mining was carried on in Chile during the domination of the Peruvian Incas, who extended their conquests to northern Chile and taught their rudimentary art of mining to their less civilized neighbours, or "mapauches," as the aborigines of Chile called themselves. There is ample evidence furnished by the discovery of very old workings made by the ancients, where crude wooden tools such as hammers, shovels, and gads, leather "capachos" or skin bags, as well as mummies of the Indians themselves, have been found, that the Indians mined for copper, probably in the native form, which they utilized for domestic uses and for arms; while the oxidized minerals, which are of such abundant occurrence in the north were used in the making of ornaments. The Spaniards, however, paid very little attention to copper, and it was not until 1600 that they started to mine for it. The demand for copper in Chile arose out of the necessity in which the Viceroy of Peru found himself of making guns for the defence of El Callao and other ports in his jurisdiction from the depredations of English corsairs and pirates, who in those days infested the coasts of the South Pacific. The metal was found to be of such good quality that a demand for it came from Spain itself for the same object. Though since 1600 copper was mined in Chile uninterruptedly the industry did not reach much importance until after the declaration of independence which opened to Chile the markets of the world. In those early days of copper mining only the very rich deposits near the coast were exploited. Many were the causes which contributed to the stagnation of the copper industry in those times. The means of transport were very inadequate; the demand for copper was not great, and its price was low; the methods of exploitation were most rudimentary; and last, but not least, Spain levied a tax of 20% on all exports, the so-called "quintos reales." Strange as it may appear to-day, copper could not be exported through any of the Chilean ports, and had to be sent either to Buenos Aires via the Andes and Mendoza on muleback or to Callao in sailing-ships in order that the proper authorities might control the famous "quintos." No wonder, then, that under such conditions copper mining could not prosper, and that only when the declaration of independence brought about the elimination of such childish and pettifogging restrictions could the industry attain a vigorous and healthy development. During the first two centuries of copper mining in Chile, the sixteenth and seventeenth, the production was only 70,000 tons, or less than a year's production nowadays.

Vicuña Mackenna, one of the most distinguished of Chilean publicists, writing on the growth of the copper industry, described it thus: "Copper was born in our mountains in a plebeian cradle, and thus lived for nearly three centuries; then labour, industry, commerce, and science, together with liberty, made of it a noble potentate."

The following table gives the copper production of Chile up to 1918, in metric tons.

Years	Total output. Tons	Annual average. Tons
1600–1699	4,600	46
1700–1799	62,200	622
1800–1899	1,764,680	17,646
1900–1918	850,720	47,260
Totals	2,682,000	8,434

Production from 1898 to 1917.

Year	Tons	Year	Tons
1898	26,341	1908	42,097
1899	25,719	1909	42,726
1900	27,715	1910	38,232
1901	30,155	1911	36,420
1902	27,066	1912	41,647
1903	29,923	1913	42,263
1904	31,025	1914	44,665
1905	29,126	1915	52,341
1906	25,829	1916	71,289
1907	28,863	1917	102,527

It was not until a third of the eighteenth century had elapsed that copper mining reached much importance in the country. The struggle for independence had absorbed all the energies of the people, and the severe taxation imposed to furnish the necessary funds for the army and navy of liberation had left the nation very poor. Labour was scarce, too, for all the manhood of the country was in arms against Spain. Though Chile achieved earlier than any other Latin-American republic a stable form of representative government, and though the steadiness of her political institutions from the earliest times offer to the world the only example of a true constitutional

development worthy of the name among the welter of revolutions for which the South-American continent has become famous, the country cannot be said in truth to have reached political peace and a definite form of government until the promulgation of the Constitution of 1833. From this date copper mining, though subjected to periods of depression, the causes of which will be analysed later, has reached great proportions, and the total value of the copper exported in 1918 was 60,000,000 dollars.

In the early days only the rich deposits situated near the coast were worked. The system used was the open-cut, and the mines were worked from the outcrops down. The rich oxidized ores were smelted in charcoal furnaces of oval shape, made from baked earth and perforated at regular intervals by a series of holes to establish a draught. Near the hearth there were two openings, one to tap the copper, and the other to admit an air-pipe leading to powerful bellows to increase the natural draught. The ore and fuel were charged in alternate layers. The wood used as fuel was cheap, for in those early days the districts round Coquimbo and Copiapó, where copper mining and smelting began, were heavily forested, though to-day they are devoid of trees. This early method of smelting was essentially a reduction of oxidized ores by charcoal, and was the only kind of smelting known and practised in Chile for over a century, until a distinguished English metallurgist, Charles S. Lambert, introduced the reverberatory furnace in 1834. Chile owes to Lambert a great debt of gratitude, for until his arrival in the country scientific and modern methods of smelting were totally unknown. Lambert was a graduate of the famous Polytechnic School of Paris, and came to Chile as assayer to an English mining company operating at Copiapó. He was long and honourably connected with mining and smelting operations in Chile, where he acquired a large and deserved fortune, and he died in London in 1877. Besides the reverberatory, he also introduced the blast-furnace, the steam-engine, stamps, sulphuric-acid making, concentration, and the use of coal in smelting ; but of all these innovations none was of such paramount importance as the reverberatory furnace, which soon made Chile the leading copper-producing country in the world. At the time of Lambert's death (1877) Chile produced more than half the world's copper.

One of the most famous copper mines of Chile in those days was that of Tamaya, near the town of Ovalle, in the province of Coquimbo. This renowned mine, reputed to have been the richest in the world, is said to have contained a "royal" or "mother" vein, fourteen yards wide, with an average tenor of 60% copper. The owner of the property was very successful in the treatment of the oxidized portion of this magnificent ore-body, but could do nothing with the ore from the sulphide zone, for in those days the smelting of sulphide ore was unknown in Chile. Ludicrous as the fact may appear to us to-day, sulphide ore was regarded as waste by the miners of that epoch, and was either thrown on the dumps or kept in the mines as filling material. Therefore, at that time the reaching of the sulphide zone was to the miner the end of his mine, the death of his hopes. The Chilean mining expression, "Se bronceó la mina," which means that the region of sulphide ore has been reached, became synonymous with the English "petering out" ; for, as sulphide ore was not marketable in those days, from a financial point of view, the mine was as good as exhausted. Lambert, who was already in the country, heard of the great riches of the Tamaya mine, then famous throughout Chile, and visited it in 1834. He marvelled at so much wealth lying idle, both inside the mine and out, and proposed to the owner to pay for the ore at the flat rate of an "onza" per day, or seventeen dollars. The owner, a most worthy gentleman, accepted, not without some misgivings as to the right mental balance of the Englishman, and in order to be in peace with his religious conscience insisted that a proviso be inserted in the contract whereby no dues were to be paid on Sundays or any fête days consecrated to the Holy Catholic Church.

When the rich and easily accessible deposits became exhausted, the production of copper in Chile decreased rapidly, and in 1882 the United States displaced Chile as the leading copper-producing country in the world. In a period of twenty years, from 1877 to 1897, the production had decreased from 47,000 to 21,000 tons.

From this brief description of the history of copper mining in Chile, it can be seen that the industry has been subjected to many fluctuations and vicissitudes. Three distinct periods of great activity in copper

production can be seen. The first corresponds to the exploitation of the rich oxidized portions of the most accessible deposits, which were mostly situated in the Coast Range or in the spurs of the Andes that run towards the coast and form the transverse valleys. These rich, oxidized ores were smelted in charcoal furnaces. The methods of mining were most rudimentary, as no mechanical equipment was used. The smelting, too, was simplicity itself. Labour was plentiful and very cheap, The second corresponds to the introduction of the reverberatory furnace, which allowed the sulphide ores, regarded as untreatable until then, to be smelted. In this second period, which lasted from 1834 to 1880, the copper produced came from the zones of secondary enrichment of the mines whose oxidized regions had been worked in the previous epoch, and from many newly discovered deposits from which only the richest ore was taken out. All these mines were situated in regions of easy accessibility; for the methods of working were still very little better than those of the previous period, and with any such methods only rich ores could pay the heavy mining costs and dear transport rates of those days. From 1880 to 1908 the yearly output was much below those years when Chile occupied first place among the nations as a copper-producing country. The reasons for the falling off of production are not difficult to discover. In the first place the richest and most accessible deposits had been worked out. Modern equipment and sufficient capital were lacking, as the nitrate fields were attracting preferably the local savings. The railway system of the country was very undeveloped, and labour was much dearer and scarcer, owing to the demands of the nitrate fields. The last period begins in 1908, and corresponds with the arrival in Chile of powerful foreign capital, first English and French, and later American. It is the era of modern machinery and methods, of the blast-furnace, flotation, and lixiviation. It is characterized by the courage, energy, and method with which American capital, scientifically directed, has attacked such tremendous undertakings as Teniente, Chuquicamata, Potrerillos, and La Africana. It is the day of the big low-grade deposits in the inaccessible regions of the Andes and of sound scientific mining engineering.

The successful development of the four great American companies in Chile, two of which have reached the producing stage, have proved conclusively that low-grade propositions are just as susceptible of profitable operation in Chile as in the United States, in spite of the much greater natural obstacles to be overcome, distance from base of supplies, and cost of transporting the produce to New York for refining or sale, if sufficient capital is provided and the management is entrusted to engineers of proved ability and experience in large-scale operations of this kind. It is my opinion that in the future the American companies operating in Chile will be able to produce their copper for several cents less than those operating in the United States, probably at about 7 or 8 cents per lb.

There is no question that local capital would not have dared to tackle such enterprises as the low-grade copper deposits of Chile, which demand the investment of millions of dollars before the producing stage is reached. Native capital is shy and conservative, and though adventurous enough for mining on a small scale, it would not have braved the big undertakings, where the payment of dividends might be long deferred, owing to its lack of experience in financing, engineering, and management.

It may be said confidently that the bulk of the copper produced in Chile in the future will come from the large low-grade mines. Whether Chilean capital, inspired by the example set by the American companies, will take heart and develop some of its own low-grade deposits is a moot question. If it does it will have to abandon its timorous present methods of financing and management, and above all repent of its inveterate love of share juggling at the Bourses, of which we have had so many glaring examples of late. Mining, we all know, is a legitimate gamble. The phrase has so often been repeated and accepted by everybody that it has become a common truism; but its meaning only holds true so long as the interests of the shareholders are dutifully safeguarded by directors and management alike. When these inflate or depreciate, bull or bear the stock of a mining company to further their own ends, the operation is neither mining nor gambling. It simply becomes common straight swindling. There has been too much of this sort of thing in Chile of late. The sooner it is abandoned the better for all concerned.

MINING CONDITIONS IN CHILE.—From the conquest to the declaration of independence, mining in Chile, as well as in all the other Spanish colonies in America, had to bear a very heavy duty in the form of the famous and much hated "quintos reales," which consisted in the payment to the Spanish Royal Exchequer of 20% of the total value of the mineral produced. Mining was a profitable undertaking in spite of such a burdensome load, owing to the fact that the miner could draw upon a large and cheap supply of Indian labour. This labour was so cheap that it received no payment in cash, and only sufficient food to keep it alive. Towards the end of the eighteenth century slavery was abolished in Chile. After the abolishment of slavery the wages paid to the Indian and "mestizo" miners were very low, and not until the middle of the nineteenth century did they rise perceptibly. The rise in wages coupled to the gradual descent in the price of silver at that time caused a slump in the production of that metal. The fluctuations in the price of copper also militated against the steady production and growth of the copper-mining industry; and though the miner after 1810 was no longer compelled to pay the exacting tribute of 20% to Spain, this advantage was offset by the rise in wages and the low price of the metals.

In those early days the production was greatly encouraged by the very cheap means of transport, for, though the roads were very bad and far between, the miner was entitled by law to graze his animals in neighbouring pastures without any payment on his part. The wood for smelting the ores could also be obtained for nothing from the near-by forests round the districts of Coquimbo and Copiapó, in those days plentifully supplied with trees, though to-day sadly deforested by the wanton and blind destruction brought about by the local smelters.

All the gold produced in Chile in early times was recovered by the Indians in the "batea," the Spanish equivalent of the English pan. Not until the seventeenth century did the "trapiche" or crude forerunner of the Chilean mill make its appearance. In the eighteenth century amalgamation was introduced in Chile, chiefly in connexion with the extraction of silver from its ores. Copper ores, until the introduction of the reverberatory furnace, were always smelted in the crude mud-baked furnaces already described. The mining and metallurgical methods employed until recent times have always been of the crudest. According to a historian, even in the early days of the nineteenth century, there was not a single trained metallurgist in Chile.

LETTERS TO THE EDITOR

Indian Mining Laws

The Editor:

SIR—Your Editorial and extract from the *Journal of Indian Industries and Labour* set out the principles that govern the granting of prospecting licences and mining leases in British India, and present the views of the Government of India on its own laws.

Having been mining for some years in this country I think it desirable that the views of some of those who have to work under these laws should also be presented, and that certain failings in them should be pointed out.

Too much is left to the discretion of the Deputy Commissioner or Collector of a district, who is not infallible, and the rules are not sufficiently binding to prevent favouritism, influence, or persuasion from affecting decisions.

To commence with, anyone is at liberty to explore for minerals, but no discoverer is allowed to take out a licence or lease on what he has found unless he be granted a certificate of approval from Government, that is, the Deputy Commissioner or Collector of the district. In other words, that he be considered by this individual to be a "fit and proper person."

Cases have arisen in which certificates of approval have been held under some collectors and renewal refused under others, and vice versa. Also a person while working for a firm may be considered "fit and proper," but may be no longer so when he wishes to do some prospecting on his own. In the event of a refusal, appeal can be made to the local Government, but the chances are greatly in favour of the district official being supported, and the Government are not obliged, and often decline, to give any grounds for such refusal. If prospecting is to be stimulated, the finder should be in a position to reap the reward of his labour. Where the application for a prospecting licence has to go up to the local Government, the licence may take anything from six to eighteen months, or even longer, before it is executed.

No limit is placed on the area taken up under a prospecting licence, with the result that a big company can tie up such parts of the country as seem desirable for a period of three years.

In mining leases, the royalties discriminate between precious stones, gold and silver, and other metals and minerals, while that on iron ore is absurdly low even allowing for a desire to stimulate the iron and steel industry of India. The minimum rates can be exceeded in the event of the deposit proving to be of more than normal value, which is not only ambiguous, but would seem to preclude the miner or investor from reaping the full benefit of the occasional windfall and encouragement necessary for further effort alluded to in your Editorial. In the event of any disputes occurring regarding licences or leases the decision of the local Government is final, though it has no official with sufficient technical knowledge to arrive at a correct decision, the Mines Department being under the Government of India.

Turning to prospecting and mining generally, encouragement varies with the officer in charge of the district, and the backing behind the prospector; while travelling in areas remote from the railway is practically dependent on the support of the local authorities.

Again, in some districts where roads have been made these are closed to both lorry and tractor traffic when no other routes are available, and one is obliged to fall back on the prehistoric bullock cart, which makes mining impossible.

The lack of encouragement to the small prospector and his inability to procure a licence has often in this country led to the premature flotation of large companies, before the necessary development work has been done, with, generally, disastrous results.

Oil in Sussex

The Editor:

SIR—The recent reports in the daily Press of the occurrence of oil in a water-well at Bosham, near Chichester, recall to mind a similar discovery at Peterborough some years ago, when a leakage from surface stores caused the "mysterious" accumulation; in this more remarkable instance in Sussex we are informed that over 100 gallons of oil have been obtained, and, further, that there are no contiguous stores from which it could possibly have been derived. Under these circumstances the belief has grown that the occurrence is a natural one, and already an inspector from the Petroleum Department has paid a visit to the well.

In the *West Sussex Gazette* of October 13 last, a short account of this visit to the Bosham well was given, and it was stated that "the inspector made no definite pronouncement on the subject, but it was gathered that he was distinctly of opinion that the oil is 'natural oil,' and not the result of some fortuitous leakage from surface stores." This, of course, is yet another example of that curious optimism prevalent whenever a new "oil discovery" is made in this country, an optimism which takes no account whatever of the obvious technical difficulties existent. The result is that there are already people who believe that at Bosham we have a potential British oilfield, and who are presumably only waiting in anxious anticipation of the prospectus of the company which might possibly be formed to undertake its development! Let us glance briefly at the scientific facts.

Bosham is actually situated on chalk, here brought to the surface by an east-west flexure known as the Portsdown Anticline; we may regard this fold as a subsidiary element of the main Weald structure; it has, in fact, a tectonic relationship to the main chalk outcrop of the South Downs. We may therefore admit the existence of a favourable structure to oil accumulation at Bosham, but that is unfortunately as far as we can agree with the "optimists." Chalk and oil do not mix, either physically or genetically. This may seem an unpardonable platitude, but the remark is necessary, since under no circumstances can the oil be indigenous to the chalk at Bosham, the latter rock being essentially a permeable deep-water deposit. Whence can the oil have come? If a natural occurrence, it must have been derived from a much older stratigraphical horizon. We may rule out at once the Lower Cretaceous beds, as these are quite barren of oil wherever met with in South-Eastern England. We have, therefore, to estimate the probabilities of the Jurassic rocks, more especially the Kimmeridge Clay, that inevitable "bonanza" of the advocates of oil-finding in Eastern and South-Eastern England. Now, quite apart from the facts that the Kimmeridge

Clay is lithologically unsuited to the existence of large quantities of oil, since it contains no intercalated sand lenses as storage pools, and that nowhere in this country has it yet yielded even a small amount of natural crude oil, its great depth of location beneath Bosham is such as to preclude the very slightest chance of the oil having migrated thence to its present position, particularly when we consider the intervening impervious horizons such as the Purbeck shales, Weald and Gault Clays. Thus geologically the possibilities of this oil being a natural occurrence are practically negligible.

To the writer a simple explanation of the facts presents itself. Bosham has a tidal creek, which drains into the Chichester Harbour, the latter having direct communication with the Channel. In these days of oil-fired ships and oily sea-water, floating oil may well occur, and under favourable tidal circumstances find its way to Bosham Creek. Local contamination of water wells would ensue if by any means the tidal water got access to the ground water, by no means an impossibility in an area situated as Bosham is. Whatever be the explanation, however, it is certain that on geological grounds no natural accumulation of oil can be expected here, and the public would be well advised to accept this and any future reports of a like character, with the utmost reserve.

BOOK REVIEWS

Technical Methods of Analysis. Edited by R. C. Griffin. Cloth, octavo, 660 pages, illustrated. Price 33s. New York and London: McGraw-Hill Book Company.

This work, the latest member of the well-known "International Chemical Series," constitutes "a representative selection of analytical methods which have been adopted as standard procedures in a large commercial laboratory engaged in technical analysis." In view of the enormous field covered to-day by the term "technical analysis," it is obvious that, to keep the bulk of the work within reasonable limits, and at the same time to describe the processes in sufficient detail, some of the sections escape the thoroughness of treatment to be found in larger works. Nevertheless, in some 600 pages the author has contrived to include a vast amount of information upon subjects of great diversity.

The work is divided into eleven chapters, each of which is devoted to a particular branch of analysis. In some of these chapters the necessary compression has resulted in unevenness of treatment, but in most instances the omissions are not serious. The first chapter deals with the preparation of reagents, standard solutions, and indicators, and with the care of platinum ware. Then follows a chapter on general inorganic analyses, where in forty odd pages a number of typical determinations are given, including such diverse materials as table salt, native sulphur, and agricultural insecticides. In the next forty pages methods are given for the examination of thirteen organic compounds of commercial importance.

The section of the analysis of metals is one which betrays lack of uniformity in treatment. The whole range of metallurgical analysis, both ferrous and non-ferrous, is disposed of in sixty pages. The sampling of iron and steel receives little more than one page. One reliable method is given for each constituent of straight steels and pig, while alloy steels are adequately treated. Brasses, bronzes, white metals of all types, and nickel silvers receive detailed consideration. The commercial analysis of spelter is described, but no reference is made to crude or refined copper, soft lead, or the various grades of gold and silver bullion. This chapter confines its attention to the metals themselves, and omits the consideration of the metallic ores, with the exception of those of tin. We should hesitate to employ the method given in the latter case for any but the cleanest or richest of materials, although the situation is saved by a reference to the assay of solder, described elsewhere in the chapter.

Succeeding chapters deal with solid, liquid, and gaseous fuels, paint, oils, fats, waxes, soaps, paper, materials, textiles, and foodstuffs, while in a final chapter devoted to "Miscellaneous Analyses" we find such strange bedfellows as boiler waters, leather, soldering, paste, and portland cement. The presentation of the book is admirable, in the style familiar to the readers of the previous works of the series. The book is not free from the orthographical blemishes common to most books of American origin, while here and there a looseness of expression is noticeable, not such, however, as to be of serious import in a book of this nature.

No attempt has been made to include the treatment of gas analysis, or the analysis of minerals metallic ores, rocks, the rare metals, or of organic dyes and drugs, nor has space permitted any mention of the theoretical aspect of the subject. While much has of necessity been omitted, the methods given are in the main up to date and sound. The information given is supplemented by numerous references to current literature, and to government publications, while the omissions are compensated for by an excellent bibliography of all branches of chemical analysis. Though both the student and the specialist may occasionally seek for information in vain, the book should prove of value for general reference.

B. DRINKWATER.

Mine Accounting and Cost Principles. By T. O. McGRATH. Cloth, octavo, 260 pages, illustrated. Price 24s. net. New York and London: McGraw Hill Book Company.

The exploitation of large mining fields, the operating of low-grade mines, and the control of a number of mines by one company from a central office, have all assisted the growth of a highly organized method of mine accounting and costing. Within the British Empire, mining fields such as the Witwatersrand, Kalgoorlie, and Kolar, have done much to place mine accounts and mine book-keeping on a regular basis. In the present work Mr. T. O McGrath, an experienced American mine accountant, presents details of American mine accounting and cost principles. The object of the author, as set forth in the preface, " has not been to exhaust the subject of accounting and costing as applied to mining, but simply to state the principles and to present sufficient forms, charts, records, and procedure to illustrate how the principles are applied in actual practice." Articles have appeared from time to time in American technical papers giving details of accounting and costing at different mines, but in this book the general principles of the subject are given clearly and concisely, and an appeal is made for the standardization of this branch of American mining administration. The author frankly admits the difficulty of applying one method and set of forms and charts for all mine accounting, and the impossibility of attempting such a thing for costing, but at least there are certain general principles that can be followed in every instance which will facilitate comparison at different mines.

Mr. McGrath deals with his subject in an interesting and orderly manner; first, in order to determine the basis of the accounting, the business is analysed and a statement of the principles of the mining business is drawn; second, charts of accounts are created which correctly reflect these principles upon the ledger; third, schedules are drawn showing the charges and credits to these accounts to ensure uniformity and correctness; fourth, books and records are created that will allow the compiling of operating and business data so as to give a balance-sheet showing the true condition of the business and a profit and loss statement that gives the results of a period's operation. The section on cost accounting deals with units of organization of work and equipment, expense, cost factors of production and operation, and time, and closes with examples of compiling the costs. The book should be very useful to mine accountants and mining engineers. The McGraw-Hill Book Company are the publishers and, as is usual with this firm, the book is handsomely bound and printed in clear type on good paper.

A. YATES.

First Aid and Rescue Work in Mining. By LOUIS G. IRVINE, M.A., M.D. Limp cloth, pocket size, 360 pages, illustrated. Price, 8s. 6d. net. Johannesburg: The South African Red Cross Society; London: THE MINING MAGAZINE.

Although statistics show that from the standpoints of health and safety mining compares very favourably with other industrial occupations, all serious attempts to increase the efficiency of emergency work in dealing with accidents are worthy of attention. Promptly applied, a knowledge of first aid may sometimes save a limb and may not infrequently save a life. Efficient first aid often prevents dangerous consequences following upon an injury, and will always tend to lessen pain and suffering. These facts are so generally admitted that they are recognized in the legislation of those countries where mining is an industry of importance. Successful candidates for competency as mine managers in Great Britain must possess some knowledge of first aid, and in the Union of South Africa, on mines employing over 500 persons, every

official (a term which includes even the chief surveyor, the foreman smith, and the mine sampler) is required to be in possession of a certificate from a recognized ambulance association testifying that the holder is qualified to render first aid to the injured, with special reference to mining accidents.

In Great Britain, the Colonies, and the United States much valuable work has been done by associations specially formed to promote the study of first aid work on mines. As an excellent example of these organizations, attention may be drawn to the Yorkshire Collieries Ambulance League. Founded in 1906, it endeavours to disseminate knowledge of ambulance work by public competitions and exhibitions by teams of mine workers. The competition, as far as possible, is confined to practical mining work, and members of each team competing for the shield and medals must be employed at some one mine in Yorkshire. Associations on somewhat similar lines exist in many other important mining fields, as in the Transvaal. The South African Red Cross Society has done much to minimize the effects of accidents on the Rand, and at the request of their Executive Committee Dr. Louis Irvine, in 1913, prepared a small volume on *First Aid in Mining.* It was realized that in the mining industry there were liable to occur many accidents on which there was little or no specific information in the first aid manuals in general use. Among these may be mentioned blasting and "gassing" accidents, due to irregularities in the use of explosives and cyanide poisoning on gold mine reduction works. The transport of injured is also a subject which demands special attention underground, for it may be necessary to take a patient through passages of small sectional area at any inclination from the horizontal. The publication of eight years ago was only intended to deal with the requirements of metalliferous workers. Dr. Irvine's latest work is much more extensive in character. It deals with general practice and accidents peculiar to both coal and metalliferous mining, in a volume of 350 pages. The book, however, may be conveniently carried in the pocket. Part I, General Course in First Aid, may be regarded as an excellent manual for the requirements of the general reader and for those studying for ambulance team competitions. The avoidance of technical details of anatomy and physiology, as far as possible, adds considerably to the value of what is by no means an elementary treatise. Part II deals with First Aid and Rescue Work in mines. The divisions in mining practice which have long existed between coal and metalliferous work are being gradually broken down, to the advantage of both sections of the community, and engineers may claim that each branch of the profession is learning much from the other. Metal miners may be surprised to find that accidents from explosions from firedamp have occurred in gold mines on the Rand and in Australia. Though the coal miner may not run much risk of "gassing" by fumes from explosives, he may with advantage learn what are the possibilities of danger in this direction.

Dr. Irvine deals with the causes and effects of gas and coal-dust explosions and what methods may be adopted for the prevention of underground fires and explosions. He states that the chapter in his book on the "Use of Rescue Apparatus in Coal Mines" is intended to be a general indication of the scope and necessary limitations of self-contained breathing apparatus, with descriptions of the most important types. In 35 pages of a small book he gives, however, much more than the preface would lead the reader to expect. It is more than a practical introduction to the subject, and for those who wish to make a further study of mine rescue work he gives a list of publications which may be studied with advantage.

In a prefatory note to the book, Dr. J. S. Haldane, whose valuable work for the reduction of mining dangers is well known, says: "I most heartily commend the book to all English-speaking mining communities." Readers will generally endorse this statement. It is a first-class textbook for the miner who wishes to specialize on first aid. It is difficult to point out defects in this admirable publication from South Africa, and critics will find little for discussion, but one or two points may be raised.

Ammonia and bicarbonate of soda are mentioned as suitable reagents for the treatment of stings by insects, such as wasps, bees, and mosquitos. As it is frequently stated elsewhere that the poison from bees and wasps are of different character, being acid and alkaline respectively, different treatment is desirable.

It is a pity that a book of 348 pages, which merits long and careful study, and may be frequently used for reference purposes,

is not given a better binding than that which may be described as limp cloth. In many instances the volume may suffer disintegration before the reader throws it aside as of no further value, so it is to be hoped that in a future edition this admirable treatise will appear in a covering worthy of the author's efforts.

STANLEY NETTLETON.

The Metallurgy of the Non-Ferrous Metals. By Professor WILLIAM GOWLAND. Cloth, octavo, 631 pages, with numerous diagrams and illustrations. Third edition. Price 30s. net. London: Charles Griffin & Co., Ltd.

The first edition of this work was published in May, 1914; the second appeared during the war, in October, 1917; while the third edition has just passed through the printer's hands; there is thus an interval of seven years since the first appearance of this book. During this interval great advances have been made in the metallurgy of the non-ferrous metals, and it has been the author's aim that the present edition shall be absolutely up to date in every respect. A careful perusal of the book will show how thoroughly this has been done.

In the second edition Professor Gowland considerably expanded the sections relating to copper, zinc, nickel, and gold, and many descriptions were added of the actual equipment and practice at typical works. Fortunately this excellent method of indicating the principles on which new processes depend has been further extended in the present edition.

The book is divided into eighteen sections under the following headings: I, Refractory Materials; II, Roasting; III, Fluxes and Slags; IV, Copper; V, Lead; VI, Gold; VII, Silver; VIII, Platinum; IX, Mercury; X, Zinc; XI, Cadmium; XII, Tin; XIII, Nickel; XIV, Cobalt; XV, Antimony; XVI, Arsenic; XVII, Bismuth; XVIII, Aluminium. The plant and processes described are illustrated by no less than 217 diagrams.

In the section dealing with refractory materials, an account is given of zirconia, which, until comparatively recent times, was considered one of the rare oxides. This mineral is now found in large quantities in Brazil, Ceylon, Australia, and other parts of the world; it is one of the best refractories known, and is particularly useful for certain classes of electric-furnace work. The causes of the failure of silica bricks at very high temperatures are also discussed.

Under roasting the operation of nodulizing flotation concentrate is described. The process was originally used for certain classes of iron ore, but has since been adapted to the agglomeration of sulphide concentrates by heating them in revolving cylindrical furnaces.

In connexion with the metallurgy of copper, it is shown that the reverberatory is rapidly displacing the blast-furnace owing to the use of powdered coal and oil as fuel. However, the blast-furnace will not be completely eliminated, as, especially in many small works, and even in large ones, there are conditions when the blast-furnace can be advantageously used. The rapid advance of the flotation process for the concentration of copper ore is largely responsible for the increased use of the reverberatory, since the concentrates are very finely divided and are therefore unsuitable for smelting in a blast-furnace.

An interesting description is given of the Bunker Hill smelter and refinery at Kellogg, Idaho. Here the furnace product is not shipped as lead bullion, but is further treated and is eventually marketed as refined lead, silver, and gold. This plant is the newest and most complete of its kind in the United States.

The author points out that the chief recent advances in the metallurgy of gold have been: (*a*) The introduction of precipitation by charcoal at Yuanmi, West Australia; (*b*) The use of cyanide solution, followed by sodium sulphide solution for the extraction of gold in a carbonaceous schist; (*c*) A modification of Miller's process; (*d*) The increased use of the Crowe process. The last-mentioned process consists in removing all the dissolved air from pregnant cyanide solution by breaking it into a spray and submitting this spray to reduced pressure produced by a vacuum pump. The occluded air is thus removed from the solution. Dissolved oxygen in the presence of zinc causes re-solution of the precipitated gold or silver, hence the advantage of its elimination. The gold and silver are subsequently precipitated by means of zinc dust.

In the section relating to the treatment of mercury ores, important innovations are described, especially the revolving cylindrical furnaces at the New Idria mine and a Herreshoff furnace at New Almaden.

Under zinc, a description is given of the

new electrolytic plant of the Anaconda Company, and of the new plant of the New Jersey Zinc Company for the preparation of zinc oxide. Accounts are also given of new furnaces for roasting and distillation.

The work as a whole is particularly free from errors, typographical and otherwise, while its value is enhanced since the author has taken great care to give in the text the source of each quotation and illustration.

Professor Gowland states in the preface that his purpose in preparing this edition has been "to make it a useful standard of reference to the principles on which metallurgical operations are based and their application in modern practice, both to students and metallurgists engaged in their profession, and it is his earnest hope that this aim will be attained." We are confident that this desire will be more than fulfilled. Further, we would congratulate the author on the production of a volume which is not only of the utmost value to the student but also to the professional metallurgist.

W. H. MERRETT.

☞ Copies of the books, etc., mentioned under the heading "Book Reviews" can be obtained through the Technical Bookshop of *The Mining Magazine* 724, Salisbury House, London Wall, London, E.C. 2.

NEWS LETTERS

TORONTO

October 10.

PORCUPINE.—For some time there have been serious apprehensions of a shortage of electric power during the coming winter, which would considerably curtail mining operations. Owing to the drought which prevailed during the summer the level of the lakes and streams was unusually low, but recent heavy rainstorms have somewhat improved the situation. The demands of the mining companies for power, however, are about 25% greater than last year, so that it is still somewhat doubtful whether an adequate supply can be regarded as assured. The power company is building a dam which is planned to raise the main storage area by 10 ft., but it can hardly be completed in time to be of service this year. The leading producing companies are preparing to install auxiliary steam plants in case is should be found necessary.

The Domes Mines, in driving on the 7th level, has encountered a large ore-body, the gold content of which is stated to average $40 to the ton. It is of irregular outline, extending more than 30 ft. in one direction, but its dimensions have not yet been determined. The ore-bodies which are being opened up on the 1,150 ft. level have been found to extend downward for at least 200 ft. A rise is being made from the 1,300 ft. level on which development will be pushed before sinking deeper. The mill is treating about 1,000 tons per day, with mill-heads averaging $7·50.

The Hollinger Consolidated is handling an average of 3,500 tons of ore daily, and is planning to increase the capacity of its mill to about 5,000 tons per day, provided the necessary power can be obtained, by the addition of a ball and rod mill grinding equipment. It has now a force of about 1,800 men employed.

The McIntyre is clearing the site for its new mill extension, but delaying construction operations until conditions as to power supply become more settled. The company has purchased a large quantity of machinery for an auxiliary power plant as a precautionary measure against a shortage. Ore is being taken out at a depth of approximately 1,700 ft. of a high average gold content, surpassing that obtained from the upper levels.

The Allied Porcupine Gold Mines has now unwatered the Three Nations, and is planning extensive diamond-drilling and development work on the 200 ft. level. Work has been resumed on the Hayden-Porcupine, which has been closed down for some years. Extensive development disclosed mineralized bodies of exceptional width carrying low gold content. Diamond-drilling is in progress on the Rochester, which is under option to the Nipissing of Cobalt, with encouraging results. A shaft is being sunk on the March Gold. Operations have been resumed at the Davidson Consolidated. Lateral work is being carried on, and a contract has been let for extensive diamond-drilling.

KIRKLAND LAKE.—The Lake Shore during August produced $42,274 from the treatment of 1,979 tons, being an average extraction of $21·36 per ton. The mill ran 92·33% of the possible running time. The shaft of the Wright-Hargreaves, now down 400 ft., will be put down to 800 ft., with stations for levels at intervals of 100 ft. The mill is now treating an average of 160 tons of ore daily, with mill heads averaging $15 per ton. The Kirkland Lake is taking out ore from the 900 ft., stated to run $40 to the ton. The mill is treating

135 tons daily. Good progress has been made in the construction of the Ontario-Kirkland's mill. The heavy machinery is now installed and the mill will be ready for operation in about six weeks. There is a large supply of ore in readiness, stated to carry about $15 in gold per ton. At the Goodfish mine a shaft is down about 30 ft. on a vein showing gold across a width of 6 ft. A good discovery has been made on the Granby-Kirkland property, where a vein has been uncovered, showing rich gold content over a width of 5½ ft., with wall-rock well mineralized. Surface exploration on the King-Kirkland has exposed 32 veins, enabling the management to select the most desirable location for a central shaft, which will shortly be put down. Sinking operations are in progress at the Comfort-Kirkland, where an electrically driven plant has been installed. The Kirkland Lake Proprietary (1919) has decided to deepen the No. 3 shaft on the Burnside 70 ft., so as to make it a central shaft for the operation of both the Burnside and the Tough-Oakes. The Sylvanite is putting down a new shaft, and abandoning the old workings, which are considered too small. A meeting of the shareholders of the Teck-Hughes will be shortly called to ratify an agreement with the bond-holders for the reorganization of the company, which is stated to be satisfactory to the majority shareholders. Conditions at the mine continue favourable. The addition to the mill, which will bring its capacity up to 160 tons per day, is expected to be in operation before the end of the year.

COBALT.—Conditions in the silver-mining industry are steadily improving with the increasing price of silver and the decline in the cost of materials. The Nipissing is producing silver at a cost of between 30 and 35 cents per oz., and the operating expenses of the Mining Coporation, Coniagas, and O'Brien are well under 60 cents per oz., leaving a good margin for profit. The production of the Nipissing for August was estimated at a value of $197,536, of which $172,516 was silver and $25,020 cobalt. A new vein found at the second level of shaft No. 63 was driven on for 80 ft., of which 60 ft. had an average assay of 2,500 oz. over a width of 3 in. The La Rose Consolidated is now producing silver from four mines, which are yielding about 130 tons of ore daily. The vein opened up at the 570 ft. level of the Violet property is yielding some high-grade ore, and a large tonnage of good milling ore. The shareholders of the Oxford-Cobalt have authorized the purchase of the Waldman property, and two other claims, bringing their total area up to 100 acres. Liquidation proceedings in connexion with the Bailey Cobalt Mines, Ltd., which were begun ten years since, were concluded last month, when the shareholders authorized the directors to make application to terminate the winding-up process. The directors were authorized to receive from the liquidation 425,000 shares of the stock of Bailey Silver Mines, Ltd., to hold for the benefit of the Bailey Cobalt shareholders. The report of the Bailey Silver Mines for September shows that the earnings of the Bailey mill were approximately $13,389, from the treatment of 4,466 tons of ore. The Right of Way company is in financial difficulties, having debts of $34,000 and no funds on hand. J. P. Langley has been appointed receiver.

SKEAD TOWNSHIP.—An important ore-zone has been discovered on L.S. 30, one of the properties of the Skead Gold Mines, Ltd. Eight parallel veins have been found within a width of 225 ft., having an average width of 14 in. One vein, which has been stripped for 900 ft., shows an average gold content of $29 per ton. A mining plant will be installed and active development undertaken.

VANCOUVER, B.C.

October 12.

CONSOLIDATED MINING AND SMELTING.—A conference was held recently, at the Hume Hotel, Nelson, between the president, general manager, and comptroller of the Consolidated Mining and Smelting Company and representatives of the individual mine owners in the Slocan district, for the purpose of arranging a new schedule of smelting charges. The conference was convened at the request of the officials of the Consolidated Company, which means that it is in the market for custom ores once again. Since the beginning of the present year the smelting company has offered no inducement to independent mine-owners to ship ores to Trail, as it would pay for the metal contents of such shipments only in warehouse receipts, upon which the mine-owners were unable to raise any funds at the local banks. The result has been that practically all production ceased, although several companies continued development of their properties on a reduced scale. At the conference the company made a tentative

offer to pay for 95% of the silver content, based on "New York Foreign" quotations, and 90% of the lead, based on London quotation, until such time that the domestic demand should be equal to the production, when Montreal quotations are to replace London ones, regardless of the zinc content of the ore. Such payment is to be made 90 days after the day of sampling, but if requested the company will give 90 day notes on the day of sampling. These, of course, would be readily discounted at the local banks. In the matter of rate of exchange on the sale of silver, the company is to receive 3%, and everything over that percentage is to go to the shipper. The new schedule will give shippers several advantages over the old one, which inflicted penalties for zinc in excess of 10%, such penalties increasing with the increase in the zinc content. The company has reduced its proportion of the advantage of the exchange-rate from 5 to 3%. Several of the mine-owners feel for the moment that the offer is too good to be true, but if the company lives up to its offer the new schedule undoubtedly will give a considerable fillip to mining in the Kootenays.

The ore receipts at the Trail smelter for the first nine months of this year amounted to 307,493 tons, and have surpassed all previous records for the period. The receipts for the first nine months of last year amounted to 251,735 tons, and those for the similar period of 1919 totalled 258,323 tons. Nearly 98% of the ore received this year has come from the company's own mines.

The Consolidated Mining & Smelting Company has come in for a good deal of criticism for its attitude in pushing development and production at its own mines and at the same time refusing to buy ore from the independent operators. Undoubtedly it has been very hard on the latter, but unquestionably it has been beneficial to the mine and smelter workers of the Province, as it is doubtful whether the independent operators could have kept their mines running in the face of the depressed condition of the metal market in the same way that the Consolidated, backed by the Canadian Pacific Railway, has been able to do. It is to be hoped, now that the company is in the market again for lead and copper ores, that the independent owners will bury the hatchet and combine with the company to thoroughly re-establish the mining industry of the Province.

During the first six months of the present year the Consolidated Company produced about 24,000,000 lb. of lead and 26,000,000 lb. of zinc, compared with 26,474,652 lb. lead and 38,995,390 lb. of zinc for the whole of last year. The company has an immense stock of zinc on hand, but about only 14 million pounds of lead, or about four months normal domestic demand. The Canadian lead market is a good deal stronger than the zinc one, and the fact that the Sullivan ore averages about 18% of zinc and 12% of lead probably has been one of the factors that has brought the company into the market again for silver-lead ore, for by smelting a considerable proportion of lead ore with Sullivan ore it will be possible to maintain the lead production without appreciably increasing the large stock of zinc on hand.

Van Roi.—Clarence Cunningham, one of the principal Slocan mine operators, has relinquished his option on the Van Roi mine at Silverton. Mr. Cunningham obtained an option on this property for $225,000 in 1916, paying a large instalment two years later. Since that time payment has been made only in royalties on ore-shipments. All told, some $350,000 worth of ore has been taken from the mine since Mr. Cunningham took control, and the owner of the property has benefited to the extent of about $150,000. The Van Roi, like the Le Roi No. 2, is controlled in London, and these, it is believed, are about the only two mines that are so controlled out of a large number that at one time were directed from London offices. Since the erection of the flotation plant the Le Roi No. 2 has been sending regular shipments of concentrate to the Trail smelter, so it is likely, now that Mr. Cunningham has relinquished his option, the London company will operate the mine itself. Douglas Lay, who is managing Le Roi No. 2, at one time was manager of the Van Roi mine.

Dolly Varden.—The Taylor Mining Co. has reopened the Dolly Varden mine and the 18 miles of railway connecting the mine with tide-water at Alice Arm. Though work will be confined principally to development, it is expected that some 4,000 tons or ore will be shipped to the Granby smelter at Anyox before snow closes the railway again for the winter. This generally happens about the first week in December. About thirty men have been taken on the payroll, and when the railway is closed half of these will be transferred to the Wolf mine, also owned by the Taylor company, and

development is to be continued at both mines throughout the winter. One of the compressors is being moved from the Dolly Varden to the Wolf, and the hydro-electric power station that was constructed last year will operate all the machinery at both mines.

ATLIN GOLD MINES.—The action of the Engineer Mining Co. against J. A. Fraser, administrator of the estate of James Alexander, involving the ownership of the Engineer mine at Atlin, one of the richest lode-gold mines in the Province, has been decided in favour of the Alexander estate, the judge ruling that the action had been too long delayed, and should have been brought during the life of the late Captain Alexander. The plaintiff company claimed that Captain Alexander and his associates jumped the claims and eventually obtained Crown grants to them. The company claims to have expended $40,000 on the property. Be this as it may, Captain Alexander operated the property for a number of years and took a considerable amount of gold from it by the crudest of appliances. The ore is rich nuggety gold ore, and much of the gold was recovered by crude crushing and revolving in a clean-up barrel with mercury. The Mining Corporation of Canada became interested in the property and sent engineers to examine it, and it was while returning from this examination that Captain Alexander, his wife, and the engineers lost their lives in the sinking of the *Princess Sophia*. Since that time the mine has been almost continuously in litigation. Notice has been given that the present decision is to be appealed.

MELBOURNE

September 6.

THE AUSTRALASIAN INSTITUTE.—The 1921 meeting of the Australasian Institute of Mining and Metallurgy commenced on Monday, August 22, at University Chambers, Sydney. Mr. G. C. Klug (Vice-President) occupied the chair, and in his opening remarks apologized for the unavoidable absence of the President (Professor Chapman). After the formal opening, the business meeting adjourned until 2 p.m., and members proceeded to the Mining Museum in George Street, where an inspection was made of the magnificent collection of rocks and minerals on view there.

During the day a conference was held to consider proposals to form an Engineering Council, composed of representatives from the three Federal Institutes, namely, the Institution of Engineers (Australia), the Australian Chemical Institute, and the Australasian Institute of Mining and Metallurgy. Messrs. G. C. Klug and A. S. Kenyon attended as representatives of the Institute; Dr. T. Cooksey and Mr. H. G. Smith representing the Australian Chemical Institute; Messrs. D. F. J. Harricks and G. A. Julius representing the Institution of Engineers, Australia. After a full discussion, the following resolutions were unanimously adopted :—

(1) That a Federal Council be formed by representatives of the Institution of Engineers (Australia), the Australian Chemical Institute, and the Australasian Institute of Mining and Metallurgy, hereinafter referred to as the constituent bodies, and that the name of the Council shall be "The Federal Engineering Council, Australia." Subject to the unanimous approval of the councils of all the constituent bodies, other Federal Technical Institutions may be admitted to membership.

(2) That the objects of the Council shall be to consider and act upon matters of common concern to the technical professions and to co-ordinate the activities of the bodies represented on all questions of national and general importance.

(3) That the Council shall consist of three representatives from each of the constituent bodies, such representatives to be elected annually.

(4) That the Council shall elect a president from among its members, and shall appoint such officers and make such rules for the conduct of its business as may be found necessary. The Council shall elect its president within one month of taking office.

(5) That the headquarters of the Council shall be Sydney.

(6) That the Council shall have no jurisdiction over the internal affairs of any constituent body, but its decision upon matters referred to it for decision by the whole of the constituent bodies shall be adopted by all such bodies.

(7) That the Council shall meet to deal with any question which may be referred to it by any constituent body, and in any case shall meet at least once annually. Where a representative is unable to attend any meeting of the Council the constituent body that he represents shall have power to appoint a substitute for that meeting.

(8) That notice of any question referred

to the Council by one of the constituent bodies must be forwarded to the secretary of each of the other constituent bodies at least one month before the meeting of the Council at which the question is to be discussed; this period may be varied only with the consent of all the constituent bodies.

(9) That the constituent bodies shall meet the cost of the Federal Council in equal proportions, and it is considered that the contribution should not exceed £25 per annum from each constituent body. The travelling expenses of delegates shall be met by their respective institutions.

(10) That any constituent body may withdraw from the Council by giving twelve months' notice, and after the expiry of that period it shall be relieved of all further obligations to the Council.

It was unanimously agreed that the three professional bodies represented at the conference be urged to take immediate action in the matter, so that the Federal Council may be formed at the beginning of the year 1922, and the chairman subsequently announced that the conference regarding the proposal had been very successful, and it was almost certain that a Federal Engineering Council would be constituted.

It was resolved that it be a recommendation to the Council of the Institute that the ordinary meeting for 1922 should be held at Port Pirie, South Australia. It was also mentioned that the Council was considering the practicability of holding the ordinary meeting for 1923 in New Zealand, so as to dovetail with the meeting of the Australasian Association for the Advancement of Science.

It was urged that the Institute should secure greater recognition by the Federal and State Governments. One of the principal reasons for obtaining this recognition was, it was urged, to prevent reports by incompetent persons being used for the flotation of mining and industrial companies. The chairman explained that the proposed Federal Council would, when constituted, be a power for good in this matter.

The papers presented for discussion were:

"Mechanical Methods for Allaying Dust." By P. H. Warren.

"The Artificial Ventilation of the Broken Hill Proprietary Mine." By R. T. Slee.

"Ventilation: Metalliferous Mines." By T. G. Hanton.

"A Proposed Copper Metallurgical Process." By P. Burbidge.

"The Use of Explosives in Steel Works." By R. T. Slee.

"Description of New Plant at South Mine, Broken Hill." By W. E. Wainwright and J. C. Cunningham.

"Determination of Minute Amounts of Lead in Water, with Notes on certain causes of Error." By D. Avery, A. J. Hemingway, and V. G. Anderson.

On Tuesday, the 23rd, the Institute excursion to Lithgow took place, and the visit was chiefly occupied in visiting the works of the Hoskins Iron and Steel Co. The business is owned and operated by Mr. C. H. Hoskins and members of his family. The capital of the company is £2,500,000, and there are approximately 2,500 men employed at the present time, but with the extensions that are contemplated in the near future this number will be considerably increased. The various plants operated by the company are as follows:—

The main iron and steel works are situated at Lithgow, on the Blue Mountains, 96 miles west of Sydney, at an elevation of 3,000 ft. above sea level. An engineering and cast-iron pipe works are situated at Sydney, and Rhodes, a suburb of Sydney. A colliery comprising 5,000 acres of coal land, together with coking plant is situated at Dapto, on the coast, 56 miles south of Sydney in the southern coalfield.

The company has recently purchased 400 acres of land on the coast at Port Kembla, 8 miles distant from the above colliery and coking plant, with a view to establishing a modern steel works to allow for future extensions whenever required. One of the directors has just returned from an extensive tour of England, the United States, and Canada, where he gathered information regarding the most modern iron and steel plants, in order that the new plant on the coast, together with numerous alterations and extensions to the existing plant at Lithgow, should be along the most modern lines.

The company is practically self-supporting for all its raw materials, as it owns numerous iron ore properties in New South Wales and Tasmania, together with extensive coal properties and limestone deposits.

In addition to the above they also own several manganese ore properties, containing ore of very high quality, from which many thousands of tons of high-grade ferro-manganese have been produced during the past five years.

The company holds numerous iron ore properties, which together are estimated to contain between 80,000,000 and 100,000,000 tons of good ore. The ore for the present steelworks at Lithgow is drawn from Tallawang, 100 miles north-west; Carcoar, 80 miles south-west; and Cadia, 100 miles south-west of Lithgow. The first-mentioned ore is a magnetite, containing 60% of iron; the latter two deposits are red hematite, containing 57–58% of iron. Numerous other deposits are also held about 100 miles south-west and south of Lithgow.

PERSONAL

W. J. BARNETT is on a visit to British Columbia, where he is examining alluvial gold properties.

JOHN A. BEVAN left last month for Roumania.

C. W. BOISE has returned from a visit to the Akim diamond fields, West Africa.

SIR ROBERT BORDEN, recently Premier of Canada, has been elected a director of the British America Nickel Corporation.

VICARS W. BOYLE has returned from Nigeria.

J. E. BREAKELL is expected from West Africa.

C. V. CORLESS, manager of the Mond Nickel Co.'s mines, has returned to Canada after a brief visit to England.

W. DEMPSTER has gone to Kamptee, Central Provinces, India.

J. B. DENNISON has left for Mexico.

G. A. HARRISON has returned from Roumania.

HARLEY E. HOOPER has joined the staff of the Department of Mining in the Melbourne Technical School.

ERLE HUNTLEY has been appointed general manager of the Laloki copper mines, Papua.

DUDLEY J. INSKIP leaves for South Africa on the 23rd.

LIONEL LINDSAY was married to Miss Kathleen Yone Kennedy on October 25 at St. Peter's, Cranley Gardens, South Kensington.

M. C. H. LITTLE is here from Italy.

BERNARD MACDONALD has opened an office at Parral, Mexico, as consulting mining engineer.

C. T. MADIGAN has been appointed lecturer on geology in the Adelaide University, as assistant to Sir Douglas Mawson.

E. MAXWELL-LEFROY has returned to Burma from a tour in Australia, New Zealand, Java, and the Malay Peninsula.

J. Q. MITCHELL left on October 19 for West Africa.

W. A. POPE has returned from Nigeria.

R. W. PRINGLE is examining the Umvukwe chrome deposits, Rhodesia.

G. E. STEPHENSON is home from New Zealand.

D. A. THOMSON is here from West Africa.

DR. R. C. WALLACE has resigned as Commissioner of Northern Manitoba, and has returned to his position at the University of Manitoba.

LOUIS A. WRIGHT has left Italy and expects to return to the United States about December 1.

B. RANCE, the chief engineer to the Burma Ruby Mines, Ltd., died last month.

JOSEPH W. RICHARDS, professor of metallurgy in the Lehigh University, died on October 12 in his 58th year. He was well known on this side as author of the books *Aluminium* and *Metallurgical Calculations*.

CHARLES W. WHITLEY, vice-president of the American Smelting & Refining Co., died on October 9, aged 50. He was for some years well known as the representative of this company at Salt Lake City.

DR. WILLIAM SPEIRS BRUCE died at Edinburgh on October 31 after a long illness, at the age of 54. He was one of our foremost explorers in the Arctic and Antarctic regions, and his contributions to the geology of Spitsbergen are well known to our readers.

TRADE PARAGRAPHS

THE WESTINGHOUSE ELECTRIC INTERNATIONAL COMPANY, of East Pittsburgh, and 2, Norfolk Street, Strand, London, W.C. 2, send us particulars of their Midget Storage Battery Locomotive.

HYATT, LTD., of Thurloe Place, South Kensington, London, S.W. 7, send us a copy of their new sectional catalogue dealing with the application of Hyatt Roller Bearings to colliery tubs and mine cars.

G. A. HARVEY & CO. (LONDON), LTD., of Woolwich Road, London, S.E. 7, send us new lists of a great variety of their manufactures: screens of all kinds for mines and quarries, oil-storage tanks, steel ventilating pipes, steel hoppers, etc.

RUSTON AND HORNSBY, LTD., of Lincoln, will be well represented at the Public Works, Roads, and Transport Exhibition to be held at the Agricultural Hall, London, from November 17 to 25. They will make a special show of their excavators and road rollers.

THE METROPOLITAN-VICKERS ELECTRICAL CO., LTD., of Trafford Park, Manchester, and 4, Central Buildings, Westminster, send us their pamphlet 7,855/2, relating to the choice of motors for industrial work; also a leaflet dealing with their Cosmos vacuum and gas-filled incandescent electric lamps.

THE HARDINGE COMPANY, of 120, Broadway, New York, and 11, Southampton Row, London, W.C. 2, send us their new catalogue, No. 9, dealing with pulverized fuels. Particulars are given of the application of the Hardinge conical mill to the production of pulverized coal, which nowadays has so many important applications.

EDGAR ALLEN & CO., LTD., of the Imperial Steel Works, Sheffield, send us their new pamphlet relating to carbon tool steels. This pamphlet gives practical hints on points deciding when it is economical to use carbon tool steels, and gives full working instructions, together with many tables and details bearing on this subject.

T. COOKE & SONS, LTD., of the Buckingham Works, York, and 3, Broadway, Westminster, send us their new catalogue of surveying instruments. This catalogue is of particular value to the mining engineer, as it not only contains a description of a great variety of old and new instruments, but gives full descriptions of all the novelties, and scientific explanations of new principles.

HADFIELDS, LTD., of the East Hecla Works, Tinsley, Sheffield, will be well represented at the Public Works, Roads, and Transport Exhibition at the Agricultural Hall, Islington, which will be open from November 17 to 25. This firm supply much plant and machinery used for traction on roads,

such as manganese steel rails, tyres, axles, etc. Their machinery is also of great value in the preparation of paving materials, their breakers and crushers being in general use for the production of both macadam and smaller material.

HOLMAN BROTHERS, LTD., of Camborne, send us a new pamphlet describing their Type 3 drill-sharpener. This pamphlet gives full details of the operation of this important adjunct to mine plant, with particulars of its special advantages and method of using. They also send us a pamphlet on their tools and plant suitable for colliery equipment, namely, haulages, air-compressors, coal-washers, coal cutters, coal picks, and rock-drills. Other new pamphlets deal with the Holman-Taquah log saw and with china-clay plant.

JOHN & EDWIN WRIGHT, LTD., of the Universe Works, Birmingham, send us their list, No. 100, which deals with the cross-sections of a great variety of wire ropes, with explanations of their particular applications. They also send us their pocket instrument, called the "Caliper-Clinometer," which is intended for the measurement of the inclination of ropes and their diameter, and for the inside measurement of the pulley grooves. Reference is made to this instrument in the column devoted to Recent Patents Published, elsewhere in this issue.

HEAD, WRIGHTSON & CO., LTD., of Stockton-on-Tees, and 5, Victoria Street, Westminster, send us a leather case for the shelf containing a set of their new pamphlets relating to a number of their specialties, as follow: Headgears, cages, etc.; coal-screening and sorting plant; pulley-blocks and hoists; steel chimneys and tanks; blast-furnace plant; Marcus screens and conveyors; Nissen stamp-mills; coal-shippers and hoists; Stanley cage props; Simplex air-locks; pit-cages; Lowden patent dryer; Colorado convertible discharge ball-mill; Akins classifier; Notanos patent rotary dryer; cement works plant; iron castings; and the King grinding pan.

THE CONSOLIDATED PNEUMATIC TOOL CO., LTD., of 170, Piccadilly, London, W., send us particulars of a new type of electric hammer, adapted for both stone and iron work, which they are now introducing. A practical electric hammer has been the object of much investigation. The firm can safely claim to have achieved a result which will satisfy the discriminating user. The stone hammer is suitable for nearly all classes of stone working, and gives excellent results when used for carving, channelling, and large lettering work. Trials have demonstrated that it does the work about four or five times faster than hand labour, with much more satisfactory results, owing to ease of control and convenience of the tool. The weight is 5 lb., and the overall length 11½ inches. The light riveting and chipping hammer has been through long and severe tests, and the results obtained are thoroughly satisfactory. In addition to the foregoing uses, this electric hammer makes an efficient tool for drilling holes through concrete, stone, or brickwork when fitted with suitable bits. It has already been used for this purpose with very satisfactory results. The weight is 7 lb., and the overall length 13½ inches.

THE WESTINGHOUSE ELECTRIC & MANUFACTURING CO., of East Pittsburgh, Pennsylvania, send us particulars of the contract they have secured for the supply of the equipment to electrify the Chilean State Railway between Valparaiso and Santiago, and the Los Andes branch. This contract covers the most important railway electrification undertaken since the beginning of the war, and the largest ever undertaken by an American firm outside of the United States. The main line, which is 116 miles long, is now under steam operation, and is the most important railway line in Chile. It connects the leading seaport (Valparaiso) with the capital (Santiago), while the line to Los Andes is 28 miles long and forms the Chilean State Railway section of the trans-continental line to Buenos Aires. The equipment to be furnished consists of eleven local passenger locomotives, fifteen road freight locomotives, seven switching engines, and five sub-stations of 4,000 k.w. capacity each. The 3,000 volt direct current system will be used and will be of American character. Owing to the abundance of water power in Chile, and the high price of fuel, all of the Chilean railroads will eventually be electrified, and the present project is the first step in this process.

METAL MARKETS

COPPER.—The standard copper market in London kept fairly firm until towards the middle of October, when prices tended to recede. The firmness at the beginning of the month was partially, at least, due to the rise in the price of electrolytic in New York, where 13 cents was touched. There appeared to be a little increase in American consuming demand, which might have justified a small rise in the cent price, but the suspicion was current on the London market that the movement was more or less artificial. In the meantime, the German mark began to fall to unprecedented levels, with the result that purchases by that country in America had to be restricted. An immediate consequence was a weaker tone on the New York market, which was sympathetically reflected in London values. Whatever may be said of the ultimate future, there certainly seems little to encourage purchasers at the moment. Consuming demand in this country can only be described as unsatisfactory, while Continental inquiry, though at times moderate, has suffered from the adverse exchanges. In the United Kingdom stocks of standard are gradually increasing, and seem likely to continue doing so owing to the warehousing of old metal which has been converted into rough copper. Meanwhile, despite drastically curtailed output in the United States, the large stocks in existence there prevent the curtailment in production being felt.

Average price of cash standard copper: October, 1921, £67 8s. 1d.; September, 1921, £68 0s. 11d.; October, 1920, £93 10s. 1d.; September, 1920, £96 13s. 4d.

TIN.—Values on the standard market in London fluctuated somewhat during October, but on balance prices were practically unaltered on the month. The statistics published at the end of September, indicating a substantial increase in the visible supplies of tin, had little adverse effect on values, probably because it was felt that the present low quotation discounts most of the adverse factors. A favourable feature during the month was the improving demand from the British and American tinplate works. The real malady of the tin-producing industry is under-consumption rather than over-production, and any broadening of genuine demand is therefore to be welcomed. Continental demand was on a moderate scale, though the weakness in the mark curtailed German

purchases. America, on the whole, bought little, the rising tendency in sterling being partly responsible. The Straits sold pretty freely during the month, and a feature was the arrival of good lines of Banca tin in this country. Stocks in the United Kingdom are increasing, while the Federated Malay States Government has still to find a favourable opportunity of disposing of its large holding. There are indications that production in the Federated Malay States and Batavia is to be cut shortly, and unless consumption increases this appears inevitable. Output in Nigeria, Bolivia, and Cornwall continues to be drastically curtailed, and should a serious restriction in the East take place, the general position might inspire more confidence than seems at present justified.

Average price of cash standard tin: October, 1921, £156 10s.; September, 1921, £156 17s. 6d.; October, 1920, £258 8s. 8d.; September, 1920, £270 7s. 3d.

Lead.—Steadiness was the chief characteristic of the London lead market last month, and prices underwent very little alteration, although they closed slightly higher on balance. Demand from English consumers tended to decline, but this was compensated for during the first half of the month by an active inquiry from Germany. The subsequent decline in the mark, however, compelled German buyers to restrict their purchases, and but for the firm attitude of holders, prices might well have weakened. Arrivals of fresh metal continued scanty and erratic, and dealers and consumers, unable to obtain delivery of shipment lead owing to steamer-discharging delays, were compelled to cover their requirements by purchasing ex-warehouse. This, coupled with consumers' general policy of buying only for immediate delivery, maintained the premium on early delivery metal. In the United States the market was firm, thanks to a good domestic demand. British dealers encountered fairly stiff competition on the Continent from American interests, although no offers were made on the London market. Some Burmese and Australian metal came forward during the month, but not in sufficient quantities to compensate for the shortage of Spanish lead; the outlook, however, seems favourable towards larger arrivals from the two first-named countries in the near future. As regards Mexico, the position there seems to be improving, but no metal has so far come out on the London market.

Average price of soft pig lead: October, 1921, £23 10s. 8d.; September, 1921, £22 19s. 5d.; October, 1920, £35 2s. 1d.; September, 1920, £35 7s. 6d.

Spelter.—Values on the London spelter market underwent little change during October, although sentiment was inclined to be changeable. At one time values tended to ease off, owing to fears of larger offerings from Germany in consequence of the weakness of the mark, but the non-realization of such apprehensions infused a little more confidence. An encouraging factor during the month was the continuance of the improved demand from British galvanizers. Producing countries were very reserved in their attitude, and very little metal was offered by either Belgium, Norway, or Germany. Some French spelter, however, was sold to this country, having possibly been set free by arrivals of spelter from Germany under the Wiesbaden agreement. The situation in Upper Silesia must continue to affect the market position to some extent; under the League of Nations' frontier decision, all the spelter works and nearly all the zinc mines are granted to Poland. German stocks are believed now to be of fairly manageable proportions, while Belgium, whose production is steady around 5,000 monthly, does not seem to have much metal to spare. In the United States the market has been firm, with a fair demand, and stocks are trending downwards. There appear to be good prospects of a resumption being made shortly in the English spelter industry, the Board of Trade having arranged for supplies of Australian zinc concentrates. Towards the end of the month the demand from galvanizers became less pressing and values eased slightly.

Average price of spelter: October, 1921, £26 10s. 7d.; September, 1921, £26 10s. 8d.; October, 1920, £40 5s. 6d.; September, 1920, £40 5s. 6d.

ZINC DUST.—Rather more inquiry is reported. Prices are slightly easier on the month: Australian high-grade £50, American 92 to 94% £47 10s., and English 92 to 94% £45.

ANTIMONY.—Values are lower, as follows: English regulus, ordinary grades, £35 to £38, special brands £36 5s. to £40, and 98 to 99% £25 to £28. Foreign is about £24 10s.

ARSENIC.—Cornish white is nominal at about £40 per ton, f.o.r. Cornwall.

BISMUTH.—The price is steady at 7s. 6d. per lb.

CADMIUM.—The market is quiet and the quotation unchanged at 6s. per lb.

ALUMINIUM.—There is no change to report. Domestic producers quote £120 for home and £125 for export business, while foreign metal is still offering around £100 f.o.b. Continent.

NICKEL.—Producers here are nominally asking £190 for home and export, but foreign metal is obtainable at well below this.

COBALT METAL.—Inquiry is quiet, but the price is unchanged at 14s. per lb.

COBALT OXIDE.—There is not much business passing. Black oxide is priced at 10s. 9d. and grey at 12s. per lb.

PLATINUM AND PALLADIUM.—Manufactured platinum is quoted at £20 5s. and raw metal at £18 per oz. Palladium is unchanged, with manufactured at £18 to £20 and raw at £14 to £15 per oz.

QUICKSILVER.—At the moment the market is steady, though business is only moderate. The price is £9 10s. to £9 12s. 6d. per bottle.

SELENIUM.—Powder is quoted at 9s. 6d. per lb.

TELLURIUM.—The quotation is lower at 70s. to 80s. per lb.

SULPHATE OF COPPER.—Values are easier at £28 to £30 per ton, for both home and export business.

MANGANESE ORE.—The price has fluctuated, but is lower on the month at 1s. 2d. c.i.f.

TUNGSTEN ORE.—Business is quiet, and the quotation steady at 12s. 6d. to 13s. c.i.f. for 65% WO_3.

MOLYBDENITE.—The price of 85% is steady at 37s. 6d. to 40s. c.i.f., nominal.

CHROME ORES.—The market is idle, the quotation being lower on the month at £4 to £4 5s. c.i.f.

SILVER.—Values receded during the month on balance, despite an upward reaction towards the close, owing to steady selling by India. The market received some support from Chinese purchasers. On October 1 spot bars were quoted at 42⅜d., eased to 41¼d. on the 6th, firmed up to 42⅜d. on the 8th, and after falling to 42¼d. on the 10th, rose to 42⅞d. on the 13th. By the 19th the price was down to 39⅞d., followed by 40⅞d. on the 20th and 39⅛d. on the 25th. Some support then pushed the price up to 41⅛d. on the 29th, but the quotation closed lower on the 31st at 40¾d.

GRAPHITE.—Business is quiet and values nominal Sellers still quote Madagascar, 80 to 90%, at £20 to £25 per ton c.i.f.

IRON AND STEEL.—The recovery in the iron and steel trades is proceeding at a slow rate, and the number of blast-furnaces in operation is being increased only gradually. Pig iron prices have been reduced, however, in the hopes of attracting buyers. No. 3 Cleveland is now quoted at 110s. for the home trade, whilst 115s. is asked for export. The Continent is still in a position to undercut for shipment business. Hematite is weak, and worth scarcely more than 120s. A few small parcels have been going into home consumption, but export trade is practically stagnant. In the finished departments, a big effort has been made to stimulate trade by cutting prices, and home trade quotations are roughly £3 down at £10 section basis. So far, however, it has had little effect. Export business is slow in spite of repeated reductions, and the Continent is still able to secure the cream of the export business. If costs came down to a reasonable level, British makers would undoubtedly come into their own again, for many schemes are being held up until preference can be given to our home works.

* Three months.

Nigerian Tin Production.
In long tons of concentrate of unspecified content.

Note.—These figures are taken from the monthly returns made by individual companies reporting in London, and probably represent 85% of the actual outputs.

THE MINING DIGEST

A RECORD OF PROGRESS IN MINING, METALLURGY, AND GEOLOGY

In this section we give abstracts of important articles and papers appearing in technical journals and proceedings of societies, together with brief records of other articles and papers; also notices of new books and pamphlets, lists of patents on mining and metallurgical subjects, and abstracts of the yearly reports of mining companies.

RESOURCES OF THE MEXICAN OILFIELDS

A paper on this subject, by L. G. Huntley and Stirling Huntley, appears in the September issue of *Mining and Metallurgy*, the monthly organ of the American Institute of Mining and Metallurgical Engineers. It has been written as a counterblast to recent articles which predicted an early exhaustion of many of the areas in the so-called southern fields of the Tampico-Tuxpam district, and which were interpreted in many quarters, rightly or wrongly, to indicate an approaching collapse of the Mexican oil industry. The object of the present paper is to show that the life of the Mexican oil industry will be a long one, and that Mexican oil will continue to be a large factor in the market for an indefinite time after the areas forming the subject of the previous articles have been drained.

The author first describes the various producing areas of the southern fields. The first of the large wells was drilled in 1908 at Dos Bocas. This ran wild for two months and then turned to hot salt water, which it has continued to produce ever since. Several nearby smaller wells were flooded with salt water at the same time, and the pool ceased to produce. There is thus no history of production upon which to base comparisons with other fields. This is the farthest north of the structures that lie along the crest of the main fold which intersects the coast at this point.

The initial well of any importance drilled on the Tepetate-Chinampa structure was Juan Casiano No. 7, drilled in 1910. This well produced from the pool without competition until 1917, when several other pipe-lines were completed, and the Huasteca Petroleum Co. shipped approximately 85,000,000 barrels of oil from the pool, out of a total of approximately 126,000,000 produced. The pool was finally flooded in 1920. The salt-water table moved up the flanks of the structure with remarkable regularity as the oil was drawn off. Starting from the 2,175 ft. contour below sea-level, it moved gradually up to the crest, where the pay formation lay at an elevation of approximately 1,800 ft. below the same datum. The estimated area originally underlain by oil was 625 hectares, with a vertical height to the crest of the structure of 350 ft. at the highest point.

The Amatlan-Naranjos-Zacamixtle is the next independent pool south of the Tepetate-Chinampa. It is cut off from the field to the north by a sharp saddle or fault, and is separated from the Cerro Azul pool to the south by a low saddle, which is also probably accompanied by faulting. While there are several domes along this crest which may be separated by faulting, it is considered a single producing unit in this paper. Up to July 1, 1921, this district had produced approximately 120,000,000 barrels of oil. The salt-water table had risen on the northern end of the pool from the $-2,150$ ft. contour to the $-1,660$ ft. contour, while on the southern end in lower Amatlan, where the crest reaches a height represented by $-1,550$ ft. contour, the salt water had barely passed the 1,800 ft. contour, as shown in Fig. 2. On the southern end, this rapid depletion was largely due to low porosity. In July, there was an area of about 750 hectares still producing in both sections, with a vertical oil height averaging 110 ft. It is estimated, therefore, that on the above date there were approximately 50,000,000 barrels of oil remaining in the pool. At that time practically all shipments had been suspended on account of the Mexican Government's high export taxes. At the rate at which it was being drained in January, 1921, 400,000 barrels per day, it would last approximately 125 days; at the rate at which shipments were made in May, 1921, the field will not be drained until the middle of 1922. It is to be expected that all companies having producing wells within the limits of this pool will take most of their oil from these wells while the pool lasts, reserving for the future their wells in less competitive fields. The companies that control wells in Toteco and Cerro Azul are apparently following this obvious policy. As regards the Cerro-Azul-Toteco pool, the crest of the structure reaches a considerably higher vertical elevation above the salt-water table than those to the north, which have just been

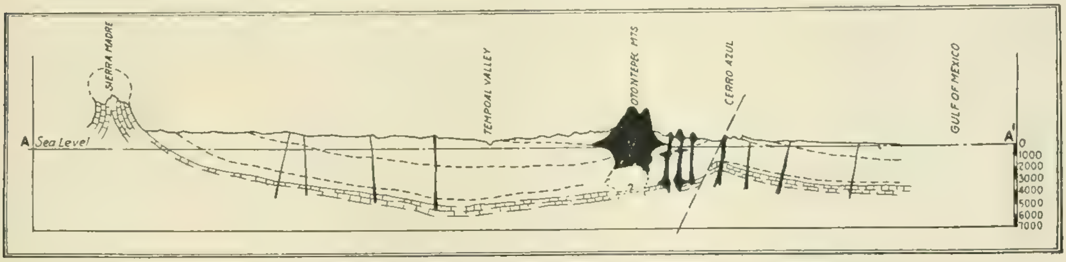

FIG 1.—DIAGRAMMATIC CROSS-SECTION OF TAMPICO EMBAYMENT

Showing main structural features and intrusives, in their relation to present and future oil development.

discussed, the highest contour apparently being −1,350 ft. The estimated area is approximately 1,350 hectares, with a vertical oil column of 450 ft. This greater vertical height of the structure represents a correspondingly greater cubical contents per hectare. By comparison with the Tepetate-Chinampa field, it is therefore estimated to contain a reserve of 150,000,000 barrels, making allowance for large amounts of gas in the reservoir in Toteco. About 54,000,000 barrels have been produced, the greater part of which has come from the Huasteca Petroleum Co.'s No. 4 well in Cerro Azul, which was drilled in 1914. This pool will be only partly competitive, as there are only three companies represented by leases and wells, although other claimants exist and may possibly obtain representation through title litigation.

The Potrero del Llano-Alazan pool, after producing approximately 117,000,000 barrels of oil, finally went to salt water in 1918. Since that time, however, by pinching in old wells and drilling strategic locations, a considerable daily production has been worked up, which was still maintained in July, 1921. The highest producing contour in this pool was about 1,750 ft. below sea-level on the Alazan end.

In the Tierra-Blanca-Chapapote pool, the first well was completed in May, 1921. The Tamasopa lime lies at approximately 2,000 ft. below sea-level in this well. In case the general salt-water level is the same on this fold as in the pools to the north (−2,250), the amount of oil to be obtained is relatively small. However, this remains to be determined. The territory is controlled by the Huasteca Petroleum Co., and it will therefore be a non-competitive pool.

The producing formation in the Alamo pool is a limestone some distance above the Tamasopa. Several pays are encountered, and at least two distinct grades of oil. Salt water has seriously invaded the small producing area, and the wells were stripping approximately 7,000 barrels per day before the shutdown. The pool has produced about 35,000,000 barrels of oil, but probably without affecting the nearby Tierra Blanca reservoir. The Alamo pool is controlled by the Penn-Mex Fuel Co., and therefore is non-competitive.

One well on the Molino pool has been drilled into a pay reservoir in the Tamasopa, at a depth of 2,710 ft.; this is the lowest producing big well in the Tampico Embayment. It is rated as a 20,000 barrel well, or better, but produces a heavy viscous oil of about 11° Bé gravity, which it has been impossible to pump to the coast. Conditions are more complex in the Tuxpam River district than in the region to the north. A good well has just been drilled in the Zapotal tract, south of the river, which produces a light oil in what is apparently the San Felipe series above the Tamasopa. It was, however, drilled deeper into the salt water.

The Panuco River pools lie along the crest of a broadly plunging arch, and produce both from the San Felipe and the Tamasopa formations. While locally there seems to be a general salt-water table below which no oil will be found, the porosity of the lime seems to be the main factor in determining its productivity in any particular area. Neither the Panuco nor the Topila districts has been finally delineated by dry holes, and there is good reason to believe that not only will they be extended, but that new areas will be brought in along the broad crest.

The value of any comparison of leases located on the crest of the folds in this region depends on the amount of oil the owners of such leases can ship and sell by means of their pipe-lines and organization during the time the total amount of oil is being depleted by all companies producing from the same pool. Also, certain wells at the extreme crests are found to continue producing for long periods when pinched in after the field as a whole is flooded. Companies that control such wells have a valuable asset as they may in the end give greater returns than the original wells.

After the Chinampa pool was drained, several wells at the crest were able to strip substantial amounts of oil by pinching in the wells, and this is also being done at Potrero and Alamo. It is expected that the Amatlan field will also offer the same possibilities. Meanwhile, the Panuco River fields to the north have not been delimited by dry holes, and continue to produce substantial amounts of oil, with the probability of increase in the future both in number and area. This may be shown as follows:—

Daily Production by Fields early in 1921 before Market Decline.

	Barrels Per Day.
Panuco River Fields	145,000
Amatlan-Naranjos-Zacamixtle	400,000
Cerro Azul-Toteco	30,000
Alamo	10,000
	585,000
Less Amatlan in 125 days will lower production to	185,000

But this disregards oil reserves from various sources, which may therefore be added and summarized as follows:—

Estimated Possible Daily Production by Fields after Amatlan Goes to Salt.

	Barrels.
Panuco River Fields	145,000
Tepetate-Chinampa (stripping)	10,000
Naranjos-Amatlan-Zacamixtle (stripping)	20,000
Cerro Azul (3 companies) (probably greater on account of sales to other companies)	140,000
Tierra Amarilla (stripping)	10,000
Potrero Alazan (stripping)	10,000
Alamo (stripping)	7,000
Tierra Blanca (non-competitive) (depending on company policy)	60,000
Total	382,000

Estimating the life of Cerro Azul and Tierra Blanca, with an estimated reserve of 200,000,000 barrels, at 1,000 days, on the assumption that they produce at the combined rate of 200,000 barrels per day after the Amatlan pool is drained, at the time of their being finally flooded, they in their turn should strip 10,000 barrels or more per day each from wells on the crests. This reserve will be partly sold to other companies and therefore will probably be pulled on much faster than this. While it is impossible to say how long this stripping can go on, there is good evidence that such wells will be long lived, as they are probably fed by oil working up the flanks of the structure over the entire former producing area. Much of this oil must have been cut off by the sudden flooding of the pools, and will now be largely available to such

FIG. 2.—STRUCTURAL CONTOURS OF SOUTHERN OILFIELDS.

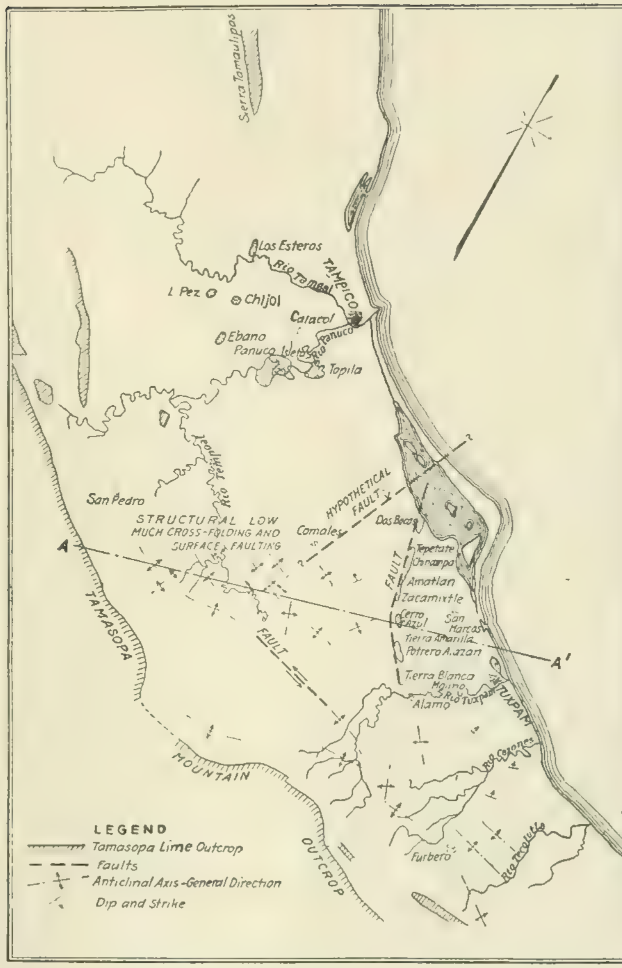

FIG. 3.—TAMPICO EMBAYMENT, SHOWING MAIN STRUCTURAL FEATURES WITH RELATION TO POOLS.

strategic wells as those mentioned. This will make it possible to estimate that, after all the southern pools have been flooded, there will still be a production in the Mexican fields of 250,000 barrels per day at the end of 1,000 days from July 1, 1921, on the assumption that the new drilling in the Panuco River field increases production. This alone is sufficient to be a considerable factor in the oil market, particularly the fuel-oil market. Meanwhile, it can be assumed that prospecting will have probably extended the producing areas in the Panuco River district, and those to the south and west of the Alamo. In the latter region there are good indications that there will be found pools of relatively light oil in sand and limestone formations above the Tamasopa as well as in the latter formation itself. In the case of the probable pools yielding from reservoirs above the Tamasopa, these will undoubtedly have smaller wells producing over a longer period of time in comparison with the large Tamasopa wells to the north. It is even possible, if later and higher prices warrant it, that this region will see pumps installed for the first time in Mexcio.

The present reserves in producing pools may be shown as follows :—

	Barrels.
Amatlan-Zacamixtle . . .	50,000,000
Cerro Azul-Toteco	150,000,000
Tierra Blanca	50,000,000
Panuco River pools . . .	?
(Have not been limited and seem capable of considerable extension)	
Total	250,000,000 plus

These amounts disregard later recoveries from the same areas through stripping wells, as the factor used in the calculations was derived from the data in the Tepetate-Chinampa area, which exclude later recoveries.

The authors proceed to discuss the geological factors involved. The oil from the fields in the Tampico Embayment has practically all been produced from porous limestone near the top of the Tamasopa limestone, or from that limestone itself. This limestone is not naturally porous, but has been channelled by underground water,

apparently associated with the igneous intrusions of late Tertiary age which are common in the field. Such cavities and channels are filled with oil on the crests of some of the main folds in the region, and, as would be expected, are filled with water down the dip on the flanks of the folds and in the basins. The large wells, however, are entirely dependent on the porosity of the limestone, and, as this porosity is apparently associated with the basaltic rocks found in certain parts of the region, it would seem to follow that where such intrusions were not present, or were infrequent, the limestone would be non-porous and wells non-productive or less productive. These conditions seem to prevail in the Tempoal Valley, and also north of the Tamesi River toward the Rio Grande, where intrusives are not only relatively scarce but in most cases are older in age than those to the south. Thus, while a few seepages exist north of the Tamesi Valley, and also in the Temporal Valley, they are as a rule small and "dead," or merely veins of asphalt or grahamite, as though leakage had long ago dissipated any possible underground accumulations of oil. The relative lightness of a few of these seepages in comparison with those found along the crests may be accounted for by considering them as filtered through a considerable vertical column of shale.

The migration of all fluids in the sedimentary formations in the Tampico Embayment must have been generally westward, that is to say, from the deep region of high rock pressures on the Gulf side in the direction of the mountain outcrop to the west. Any interruption to this migration must have been either the tops of folds, where the formations were sufficiently porous to catch and retain the oil above the general salt-water body, or fracture or fault zones which allowed it to escape to the surface, or both. In the Tampico Embayment there exists a line of folding flanking the coast, where both conditions exist. In fact, the groups of numerous live seepages at the surface were the first evidence of the fold itself noticed by the early exploiters of the field. Only remnants that could spill across the low places in the arch could get by this first line of folding. Immediately west of the crest of this first arch the number and size of these igneous intrusions increase greatly, and as each intrusion of basalt cutting through the upper formations is an outlet for the leakage of any oil underground, the territory to the westward suffers from the following disadvantages :—

(*a*) Less oil from migration ;

(*b*) More dissipation through having to pass a zone of intrusives in migrating westward ;

(*c*) General synclinal conditions favourable for water accumulation rather than oil, especially as the outcrop of the sandy San Felipe is open to infiltrating waters on the west at an elevation that would give it a head ;

(*d*) Proximity to mountain folding, with its accompanying heat and pressure, which may have destroyed some of the oil reservoirs.

The Tempoal Valley suffers from all of these disadvantages, but good structures on the flanks of such a basin may be expected to produce oil in relatively small amounts, even with a comparatively low porosity of the Tamasopa. The drilling carried on by the Pearson interests at San Pedro showed what may be expected. Such areas will be valuable as the older, more prolific fields become exhausted, particularly since this is a very high-grade oil.

The considerations that were disadvantages to the Tempoal Valley make the crest of the Panuco arch appear very attractive for the future. In the Panuco field, and the surrounding district, the oil accumulations seem to be comparatively independent of local structure and to be governed by the local porosity of the limestone. If this holds true generally, there will be a great deal more oil produced from this region, as in the northern part of the Embayment area this broad arch constitutes the first barrier to the migration of oil from the east and the south-east. The oil found apparently increases in specific gravity from the Panuco River to the north. That found at Los Esteros will barely flow.

North of the Tamesi River the Tamasopa lime outcrops in the Sierra Tamaulipas, an uplift which occurred during late Cretaceous times. Thus, this has been a leakage zone for a wide area of sedimentaries for a much longer time than leakage has been going on in the southern fields through the recent basaltic intrusives. The same conditions hold true of the zone immediately flanking the mountain outcrop of the Tamasopa, which bounds the Tampico Embayment to the west and south. Prospecting in such areas, between the first barrier to the east and the Tamasopa outcrop to the west should wait for the distant future.

From available surface evidence, and drilling that has been done up to the present time, it seems probable that the Dos Bocas-Alamo fold is plunging steeply south of the Tuxpam River. This would necessarily leave a gap in the main line of folding across which westward migrating oil could pass, to be caught by structural folds lying at the head of the sub-embayment west of this gap. Since certain of these folds are well marked, and have seepages and basaltic intrusives near their crests, they certainly give promise of favourable results when tested. These various favourable conditions are less in degree than on the structures along the present producing fold to the north and the strategic position of these folds is not so good ; but they constitute the type of structures that will be tested in the future. The chances seem good for bringing in fair-sized wells of lighter oil than the present fields yield.

As previously stated, to the south of the Alamo the evidence seems to indicate that the main fold is plunging rapidly, and will not connect directly with any fold in that direction. However, in the region between the Tecolutla and Cazones Rivers, a relatively sharp fold is found, which brings the Tamasopa lime within drilling distance of the surface. This fold apparently constitutes the first barrier fold east of the coast in this region, and as it contains both seepages and recent intrusives along its crest should constitute a good reservoir for oil. To the west and south-west of the barrier fold the Tamasopa is exposed at the surface, as is also the San Felipe. This territory cannot be considered particularly favourable, even though numerous seepages are found close to the mountain front. The general strike of the folding changes abruptly in the vicinity of the Nautla River, bringing the Tamasopa close to the surface along a fold with a N.E.—S.W. axis, which, together with the eastward limestone front to the south in the vicinity of Misantla, limits the Tampico Embayment in this direction.

In general, it may be predicted that any folds that bring the main reservoir rocks within drilling depth

along a zone flanking the coast, and which do not at the same time have their reservoir exposed, should be the best prospects for the development of oil production. The Furbero field produced from a volcanic sand found in the Mendez shales, a considerable distance vertically above the Tamasopa, while the recent well drilled by the Penn-Mex Fuel Co. at Zapotal encountered several good pay sands before reaching the Tamasopa limestone. Such folds in the extreme southern end of the Tampico Embayment area have the following advantages :—

(*a*) Well-defined structures in the same general region that has already produced oil ;

(*b*) Presence of typical surface evidence in the way of live seepages and recent igneous intrusions, which in the northern districts are accompanied by porous Tamasopa limestone underground ;

(*c*) Relatively shallow drilling depth at crests ;

(*d*) Same relative strategic position as the present producing fold north of the Tuxpam River ;

(*e*) Possibilities of additional oil-bearing formations above the Tamasopa. Both the San Felipe and overlying shales contain frequent beds of sand in this region south of the Tuxpam River.

The authors conclude by saying that it seems probable that the present fields will continue to produce oil in large quantities during the time necessary to carry on prospecting for additional pools. Certain of the areas now being explored or already in the hands of strong companies offer excellent possibilities for the development of important production. However, the opening up of these new fields will require new roads, railways, and pipe-lines, which will, in general, be longer and more expensive than the existing system of transportation, and some of which will in all probability have to be operated as units separate from those already installed. The existing transport system must in large part be liquidated out of the present producing fields. Costs of producing and operating will be higher than in the past, wells, in general, will be smaller, fields will be more disconnected. It is probable, however, that the oil in most new pools will be of a higher grade. These conditions will probably force upon the operators the use of co-operative or common carrier pipe-lines, railroads, telegraph lines, etc. In other words producing conditions will be more nearly like those of the United States than has heretofore been the case. It will be seen that the authors are fairly optimistic as to the future of these oilfields.

THE OILFIELDS OF EGYPT

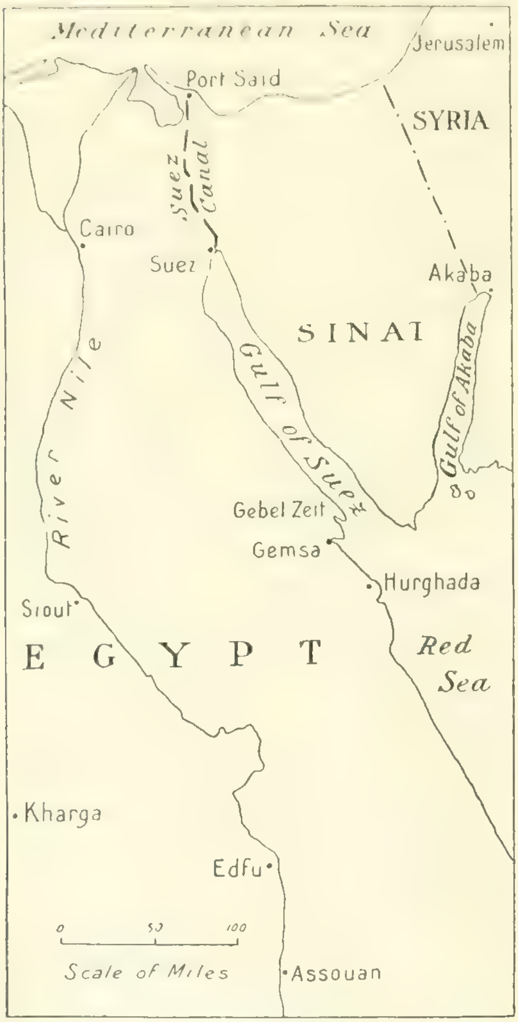
At the meeting of the Institution of Petroleum Technologists held on October 11, Dr. William Fraser Hume, director of the Geological Survey of Egypt, read a paper on the Egyptian Oilfields. We give an abstract herewith :—

The presence of petroleum in Egypt was known from very early times, its occurrence on the surface of pools at Gebel Zeit being recognized by the Romans, who named the locality *Mons Petroleus*. This now famous spot is situated at about 163 miles south-east of Suez on the western shore of the Gulf of Suez, and at the foot of a range some 1,400 ft. in height. When the Société Soufriere began the exploitation of sulphur on the peninsula of Gemsa in 1865, about 12 miles south of Gebel Zeit, tunnels were made into the gypsum containing sulphur close to the sea-shore. Considerable interest was aroused when petroleum was found to be floating on the sea-water which had collected in these excavations. The interest of the Egyptian Government in these oil occurrences began in 1884 when M. de Bäy called attention to the presence of petroleum in the old workings at Gemsa and at Gebel Zeit. It was arranged that he should undertake borings at these localities. The first boring reached a supply of oil at 106 ft., yielding 25 barrels a day, while a second well reached 137 ft., yielding 500 cubic metres a day of mixed oil and water. The Government, however, did not proceed further with the venture. In 1886 an expedition was organized under L. H. Mitchell, who was subsequently joined by Colonel Stewart, the British Consul-General at Odessa. Their results were embodied in two reports, which contained valuable data as to the distribution of petroliferous deposits in Egypt. In 1896 a new period of activity commenced with the formation of the Geological Survey under Captain (now Colonel) H. G. Lyons. In this year began the systematic geological examination of Egyptian territory, which has continued with increasing precision and detail up to the present day. This study led to the foundation of the present phosphate and magnanese industries but the visits to Gemsa and Zeit led to pessimistic conceptions of the oilfield possibilities. New impetus was given to prospecting when the Department of Mines was founded in 1906 under John Wells. Gemsa in particular was opened up, and in April, 1908, the first flowing well came in. A number of companies were formed in rapid succession after the initial success at Gemsa, but the failure of their efforts led to stagnation so far as companies were concerned, though the researches of the Government to obtain further light continued with unabated vigour. The opening up of the famous Hurghada oilfield further south again encouraged private enterprise, which, though checked by the war, has now been resumed with great energy.

With regard to the boring operations begun in 1908, No 1 well made good progress through dark limestone with subsidiary clays, and was drilled successfully to an oil rich in benzine on April 1, 1909. Other wells followed in fairly rapid succession, the first four being all oil producers, but of the twenty-one wells drilled only seven actually yielded petroleum, and of these only three were of first-class character. Though the oil itself was of valuable quality the supply fell off somewhat rapidly, and at the present time only one well occasionally has a small and very temporary production. The first geological results obtained were of a puzzling character. While the first well was entirely in limestone, those following showed alternations of gypsum and limestone in varying proportions. The oil-yielding zone was found to be a narrow belt bordering the sea ; to the westward of it the limestone diminished, the gypsum increasing in importance, while finally salt in great masses became the essential feature in a boring made to test the main anticline near Gemsa Bay. The petroleum was apparently present in porous calcareous members of a thick gypsum limestone series, the age of which has now been definitely

determined as not earlier than the Lower Miocene. Immediately an underlying sandstone was encountered (presumably the Nubian sandstone formation), the presence of oil was replaced by that of water.

The years 1908 to 1913, inclusive, were marked by an effort to determine the oil-producing possibilities of a number of small anticlines present on the main coast of Egypt, near Gemsa, and on the adjoining islands. Mr. John Wells commenced



MAP SHOWING POSITION OF EGYPTIAN OILFIELDS.

operations almost simultaneously at Ras Bahar (February 23, 1910), Gaysum Island (March and April, 1910), and Jubal Island (June, 1910), these being conducted on behalf of the African Prospecting Syndicate and Eastern Petroleum Company respectively. At the same time (June 27, 1910), the Egyptian Oil Trust began boring on Um el Haimet Island, situated eastward of Gemsa, and separated from it by a relatively shallow sea channel. The results, if instructive from the point of underground structure, were most disappointing as regards oil possibilities. At Ras Bahar the deeper No. 1 bore traversed nearly 3,000 ft. of alternating gypsum, shale, and salt; on Gaysum the same salt-containing series began at 450 ft. below surface, the salt (sometimes in continuous masses over 200 ft. in thickness) alternating with shales and gypsum to the depth attained, 2,668 ft. In the Jubal Island the results were different, where the earlier borings began in gypsum, then passed through dolomitic limestones which contained petroleum in small quantity. No large supplies had been met with before red granite was entered. Five other borings undertaken on this island showed increasing thicknesses of shale and gypsum away from the centre of the dome. The Um el Haimet borings equally indicated the presence of salt zones, their alternation with gypsum and clay, and in addition the presence of granitic sands of varying thickness distributed between 1,280 and 1,710 ft. below surface.

Drilling in 1911 and 1912 revealed the presence of the gypsum, clay, and salt series at Ramin Island, near the south end of Gebel Zeit, and also at the extreme northern end of that range, north-west of Ras Dib, near where the valley Wadi Dara enters the sea. As none of these salt-containing bores have shown any satisfactory indications of petroleum, it remains doubtful at present whether such anticlines as those above-mentioned would yield results if the deeper strata were penetrated. Another series of borings begun in 1910 were in the meanwhile presenting records of a different character, these being sunk at various localities at the southern end of the Gebel Zeit peninsula. The first was located near the surface seepage, and was carried to a depth of 610 ft., when it was abandoned on meeting the igneous rocks. Two others were begun on a small anticline north of Zeitia Harbour in April, 1911, and closed down in March, 1912. In these borings limestone played an important part, and some thin bands were saturated with petroleum, but these were not of sufficient thickness to be producers. A fourth was begun in June, 1912, and small thicknesses of salt were encountered. The work was abandoned at 1,322 ft., when granite was recorded as having been entered. So far the borings had thrown but little light on the deeper-seated structure, but one sunk on the western side of the Zeit range, early in 1913, went through a more normal succession, such as was indicated at the surface. Beneath a considerable thickness of gypsum and clay followed a fairly thick limestone which contained a certain amount of petroleum. Drilling was continued to 1,193 ft., when the Nubian sandstone was entered, a strong supply of water being then encountered. The effort was then discontinued. This boring, it should be stated, was well down the western limb of the anticline.

Up to this date the efforts to develop the minor anticlines had failed both on the Egyptian mainland and on the islands, the only oil obtained being along a line at Gemsa, which did not display striking anticlinal characters. In none of the localities tried were there any surface indications.

In 1909 it fell to the author's lot to push southward to the Hurghada anticline, and in March, 1911, his interest was greatly aroused by the discovery of an oil-smelling limestone in the western anticline of Hurghada. From this time onward, the Egyptian Government paid special attention to the Hurghada area. The Anglo-Egyptian Oilfields, Ltd., was also attracted to the region. The success of this enterprise is now a matter of history, a series

of gushers being obtained from late in 1913 to the present day.

Until 1912 the geology of the oilfield region remained wrapped in a considerable amount of obscurity. New data were, however, obtained in that year, which threw a flood of light on many points hitherto obscure. During the author's expedition of that year a young Arab chainman found a number of sea-urchins in a limestone underlying the great gypsum-clay series in Wadi Kabrit, at the northern end of the Zeit range, and further up the valley a rich fauna in the same formation was obtained containing such typical Miocene fossils as *Aturia aturi* and *Terebratula Miocenica.* These were identified as belonging to a period transitional between the lower and middle Miocene, and in this connexion it may be recalled that the late Professor Suess regarded *Aturia aturi* as the type fossil of the Schlier shallow-water formation which forms the lower section of the middle Miocene in Austria. This settled any controversy as to the age of the gypsum bordering the Red Sea.

When examining the oilfield area about 1905–6, Dr. Erb and John Wells found that a series of marls underlying the gypsum in Gebel Zeit, and in places over one hundred feet in thickness, were filled with the minute tests of the foraminifer *Globigerina.* This interesting formation was subsequently proved to extend throughout the Gebel Zeit range. The Petroleum Research studies in 1918 indicated the Miocene succession to be as follows :—

Upper gypsum beds.
Intergypseous clays and limestones.
Lower gypsum beds.
Globigerina marls.
Lower Miocene limestones, with flint conglomerates at the base.

The Gemsa oil was undoubtedly obtained from porous limestones belonging to the above series, and it is to this source that geologists look for any benzine-rich light oils that may yet be found in Egypt.

The most important advance in the knowledge of the distribution of oil in Egypt was indicated when the geologist of the Anglo-Egyptian Oilfields, Ltd., was permitted to disclose some of the results of his investigations at Hurghada to the author, in return for information supplied regarding the surface structure at Gebel Zeit. On comparing notes it was found that all representative members of the Zeit series were represented in the underground succession at Hurghada, including such characteristic members as the *globigerina* marls and the flint conglomerate. Beneath the conglomerate was a succession of fine sands and carbonaceous shales similar to beds well known in Upper Egypt as members of the upper Cretaceous formation. The lighter oils were found associated with calcareous strata in the Miocene gypsum-limestone series, the heavier oils being, on the other hand, present in the fine-grained Cretaceous strata.

This interesting conclusion brought the oil geology of Egypt proper into relation with that of the Sinai Peninsula. In 1888 Colonel Stewart learnt that petroleum was frequently found floating at low tide on the sea at Abu Durba, twenty-five miles north-westward of Tor, the quarantine port of Sinai. Oil seepages were also noted on the shore near Gebel Tanka, north of Abu Zenima, this leading to boring operations in August, 1910. The deepest of these reached a depth of 2,930 ft. Commencing in beds of Eocene age it traversed the whole of the fossiliferous Cretaceous strata, finally entering the Nubian sandstone. An oil-yielding layer was struck between three and four hundred feet from the surface, but as the supply was only three barrels a week the enterprise was eventaully abandoned. The Petroleum Research study of the Egyptian Government was extended to the Sinai Peninsula in 1917–18, detailed examinations being made of the Abu Durba and Tanka areas. It was evident that petroleum had been present in both the Eocene, Cretaceous, and Nubian sandstone formations. oil-rock being found at several horizons. The most consistent development is in the Cenomanian strata immediately above their junction with the Nubian sandstone. On the other hand, where the fossiliferous Cenomanian strata are not present, having passed into the sandstone type, the first limestone or marly strata above the sandstone show evidence of the former presence of oil, or it may be present in the underlying sandstone. Thus indications of the former presence of petroleum have been noted in almost every member of the Cretaceous and Eocene succession. Moon and Sadek have found repeated indications of its wide distribution in the Cenomanian strata of North Sinai ; at Abu Durba, where the lowest fossiliferous limestone is Turonian, the sandstone immediately below is highly bituminous, and has been proved still to contain thick liquid petroleum at only a few feet below the surface ; at Abu Zenima the oil-impregnated strata are at a higher Cretaceous horizon, the Santonian, while in the Tanka area Eocene beds have both yielded petroleum in borings and have also been highly impregnated with oil near the surface. The Cenomanian strata of Sinai are the lowest in the geological scale to contain indications of petroleum. The Jurassic strata in the northern hills of Sinai are in lithological structure most favourably developed to act as oil repositories, yet careful search has not yielded the slightest evidence of the former presence of petroleum in them. The same holds true for the Carboniferous strata in Western Sinai, and, so far as known, Wadi Araba also, on the Egyptian side.

IRON ORES IN SOUTH-WEST AFRICA

In the *South African Journal of Industries* for September, Dr. Percy A. Wagner gives an account of iron ore deposits in the Namib desert, from 10 to 16 miles to the south-east of Walfish Bay. He finds that the ores are highly siliceous, and not suitable under present conditions for use as a source of iron.

The Namib desert is for the most part flat and featureless, and, apart from its waterless character, easy to traverse. To reach it, however, it is necessary to cross the great belt of sand dunes extending along the coast from the neighbourhood of Luderitz Bay to the Swakop River. The belt is at its narrowest in the area under review, but none the less offers a most serious obstacle to transport, and the only practicable method of getting the iron ore to Walfish Bay would be by aerial tramway. The deposits are all of sedimentary origin, and, with one exception—a deposit of magnetite-garnet rock—consist of itabirite belonging to the

Fundamental Complex. The itabirite forms narrow [illegible] 50 ft. in [illegible], which in some instances run almost in a straight line for considerable distances, while in other instances the [illegible] of folding and faulting follow a sinuous course. The itabirite, being more resistant to atmospheric weathering than the other members of the Fundamental Complex, gives rise to low black ridges and kopjes which stand out prominently from the light-coloured surface of the Namib. Another consequence of the highly resistant nature of the ore is that the slopes of such kopjes, and in some instances even the flats surrounding them, are covered with black ironstone rubble, giving the inexperienced observer an exaggerated idea of the extent of the deposits. Five separate occurrences were examined. The itabirite everywhere presents much the same features, and in regard to several of the occurrences it is highly probable that they are repetitions by folding of the same bed. One of the most interesting points brought out by the writer's investigations is that there are fairly extensive ancient workings on at least two of the occurrences. These take the form of shallow pits and trenches, now for the most part filled with coarse, wind-blown sand. They are no doubt attributable to Hereros and Berg Damaras—skilled workers in iron—who inhabited the Walfish Bay territory until about the year 1840, when they were driven northward by the Hottentots of the so-called Red Nation under the redoubtable Jonker Afrikaner. The ore was probably smelted at Rooibank on the Kuiseb with charcoal made from camel thorn or other hardwood trees growing in the river-bed.

In its more typical development the itabirite is a regularly banded blackish rock composed essentially of iron oxide and quartz, for the most part segregated in well-defined layers, but sometimes intimately intermingled. The individual layers range in thickness from a fraction of a millimetre to 6 centimetres. The iron oxide is mainly specularite occurring in the form of thin plates and scales from 0·2 to 0·8 millimetre in diameter, arranged parallel with the banding or foliation. In addition to the normal specularite there is always present, in the form of small grains and crystals, a variety of greyish lustrous hematite, which may be martite pseudomorphous after magnetite. It forms impersistent layers up to 4 millimetres in thickness. Magnetite itself is only very sparingly present in these rocks. The siliceous or quartzitic bands, which vary in colour from pale-grey to dark-bluish grey, are composed essentially of a mosaic of interlocking grains of quartz from 0·2 to 1 millimetre in diameter. Many of the larger quartz grains are seen under the microscope to enclose tabular crystals of specularite arranged parallel to the schistosity, clear proof that the recrystallization of the quartz occurred during or subsequently to the foliation of the rock. Some varieties of the itabirite contain a small proportion of brownish-red garnet (almandine) in the form of irregular grains generally enclosing quartz and specularite. The garnet is sometimes imbedded in the iron oxides, but more usually occurs in association with quartz in lenticular eyes lying parallel with banding. Other accessory minerals present in small amounts are apatite and rutile.

On Von Broen's claims, situated about ten miles south-east of Walfish Bay, a bed of itabirite traceable over a distance of about 1,600 yards builds a conspicuous row of black kopjes running in a N.E.–S.W. direction along the edge of a broad expanse of gravel-covered desert known as the Plum; the kopjes themselves flanking a low, rugged, quartzite plateau. The itabirite bed appears to range in thickness from 6 ft. to fully 80 ft., the reason of this great variation not being apparent. It is intercalated with dark, fine-grained quartzite, containing a good deal of specularite in the form of minute grains and scales. The quartzite is seen at several points to be intersected by veins of coarse pink pegmatite with which the veins of pegmatitic quartz occurring in the itabirite are no doubt connected. In the first kopje the strike ranges from N.W.–S.E. to N.N.W.–S.S.E., the dip being toward the north-east. In the next, situated about 100 yards to the north-east, the strike is north-east to south-west, and the dip apparently vertical; beyond this the bed strikes toward the north, and then, again, follows a N.N.E.–S.S.W. course. To the north east of the fifth kopje the bed is cut off by a fault, and on the sixth it is seen to be disposed in the form of a closely compressed fold, the dip being practically vertical. In the seventh kopje the strike is N.E.–S.W., then approximately north and south; in the four most northerly kopjes the strike is more regular toward the north-north-east, the dip being almost vertical. The first and eighth kopjes are most prominent, and on these there are extensive ancient workings. The ore is very variable in character; it is made up of alternations of iron-rich and iron-poor layers, the former rarely exceeding a few inches in thickness. It is thus possible to obtain from the same outcrop all gradations from pure iron ore composed almost entirely of specularite to quartzite almost free from specularite. The average grade, such as would be obtained by mining on a large scale without sorting, is distinctly low. Thus an average sample of the ironstone building the first hill showed on analysis:—

	%
Fe . . .	37·7
SiO_2 . .	46·8
P . . .	0·15
S . . .	0·25

This material cannot be classed as iron ore. By selective mining and sorting a much better quality of ironstone could be obtained, but it is very doubtful whether in any circumstances a grade of over 53% could be maintained, as a picked sample of the best ore exposed on Hill No. 7 only showed 53·2% of iron and 19% of silica, and a sample of picked ore analysed some years ago in the State Laboratory at Hamburg, 53·1% of iron and 21% of silica.

A sample of itabirite from Von Broen's claims which was sent to Germany for analysis some years ago was found on analysis to contain 1·8 oz. of silver per ton and traces of gold. This led to the deposit being tested for precious metals by the engineers of the Deutsche Kolonial Gesellschaft für Süd-west Afrika. A bulk sample was taken and analysed with the following result: Iron 26·3%, gold *nil*, silver *nil*, platinum *nil*, so that in this sample none of the precious metals sought was present. The sample from Hill No. 1 taken by the writer was found, on the other hand, to contain 1·3 dwt. of silver and 3·5 dwt. of gold per short ton. It would appear, therefore, that small quantities of gold and silver are sporadically scattered through the itabirite, as is also the case with some of the itabirites of Brazil and with some of the banded ironstones occurring in the Union and

Southern Rhodesia. The amounts of the precious metals indicated by the analyses are insufficient, however, to warrant the expectation that either of them will be found anywhere to be present in profitable quantities.

On Murray's claims, situated two miles due south of Von Broen's, there is a long low ridge built up of a persistent vertical bed of banded itabirite about 600 yards in length striking N.E.–S.W., which for part of its length is paralleled on the south-east by a shorter bed of the same rock. It is probable that here are the two limbs of a very steep fold, pitching toward the south-south-west, but this could only be established by trenching. There are fairly considerable ancient workings now filled with coarse sand along the crest of the ridge. The width of the ironstone ranges from 20 yards downward. It is made up of alternations of specularite and quartzitic matter, the latter being in some instances of a cherty nature. Here, as on Von Broen's claims, it is possible to pick out specimens of very pure iron ore composed almost entirely of specularite, but the average grade is not very high. A sample taken by the writer of ore of more than average richness and probably fairly representative of the grade that might be maintained, if selective mining and sorting were practised, gave on analysis the following result :—

	%
Fe	57·7
SiO_2	17·6
P	0·05
S	0·35

A representative sample of the ore analysed by George T. Holloway & Co., Ltd., of London, showed :—

	%	
Fe_2O_3	65·32	Total iron 46·39%
FeO	0·90	
SiO_2	32·87	
Al_2O_3	0·69	
S	0·094	
Mn	0·048	
Ti	—	
Ca	—	
Mg	—	
Total	99·92	

A picked sample of the rich ore showed :—

	%
Fe	61·94
SiO_2	11·45
P	0·07

About 2½ miles to the south-east there is a similar but smaller hematite occurrence. The ore is again composed essentially of quartz and specularite, but also contains dark brownish-red garnet as an accessory constituent. It forms a vertical or steeply dipping bed some hundreds of yards in length and apparently averaging about 6 ft. in thickness. The strike is from north-east to south-west. A fairly representative sample of the ore was found on analysis to contain :—

	%
Fe	48·4
SiO_2	26·1
P	0·05
S	0·06

A mile to the south of this there is a long black outcrop formed by what may be a repetition by folding of the same bed. The ore here is much richer in garnet, this being the occurrence in which the itabirite encloses lenticular bands of a very coarsely crystalline aggregate of lustrous specularite, garnet, and bluish-grey quartz. A sample of the more typical itabirite gave on analysis :—

	%
Fe	41·2
SiO_2	30·8
P	0·06
S	0·09

The last of the itabirite occurrences to be examined is situated about 4½ miles north-west of Rooibank. It is a steeply dipping bed apparently ranging in thickness from 5 to 10 ft., the outcrop of which can be traced for about a mile. The itabirite is interbedded with coarsely crystalline white limestone containing a number of interesting contact minerals. The ore is very variable in character and its iron content probably ranges from 50% to 10% and less. A fairly representative sample showed :—

	%
Fe	38·2
SiO_2	44·5
P	0·1
S	0·3

A short distance to the south of this is a narrow belt of a coarsely crystalline magnetite ore forming a succession of low hog-backs, the total length of outcrop being about 400 yards. The ore is a coarse aggregate made up in variable proportions of magnetite in crystals and pieces up to 1 in. across, brownish-red garnet, and quartz, the magnetite predominating. It is in places distinctly banded, but, as a rule, the banding is barely perceptible. The grade is again very variable. A representative sample showed :—

	%
Fe	52·2
SiO_2	25·8
P	0·10
S	0·30

The magnetite rock is intercalated with crystalline limestone and lime silicate rocks.

Notwithstanding the unfavourable geographical situation of the deposits, it would have been practicable had any of them contained really large quantities of high-grade ore, that is, ore containing not less than 60% of iron and not more than, say, 4% of silica, to export this ore at a profit from Walfish Bay. Actually, however, while two of the deposits—namely, those on Von Broen's and Murray's claims — are of fairly considerable magnitude, none of them is, in the opinion of the writer, capable, even with selective mining and sorting, of yielding commercial quantities of ore averaging over 53 to 57% of iron and under 17 to 19% of silica. Ore of this grade, being in normal times worth only from 15s. to £1 per long ton, c.i.f., European and American ports, could not possibly be exported at a profit, as the cost of mining, sorting, and transport to Walfish Bay would be at least 10s. per ton. To send it by rail to the smelting works at Pretoria and Vereeniging would be equally impracticable, as immense supplies of this grade are available in the Transvaal. To smelt it on the spot is quite out of the question. The deposits are thus evidently not worthy of exploitation as a source of iron at present.

THE PECHEY COPPER-LEACHING PROCESS

In the July issue our West Australian correspondent gave the latest news about the Whim Well and Mons Cupri copper deposits in the north-western part of West Australia. Since then a report on this district by T. Blatchford, the Assistant State Mining Engineer, has been published. We extract herewith his remarks on the Pechey process, as used at these mines for extracting copper from the dump ores. As mentioned in July, the point of the process is the use of sulphurous acid in altering ferric sulphate to ferrous sulphate. The process has been used at the Mount Hope copper mine in New South Wales, and the information given by Mr. Blatchford combines the experience of Mr. Audley Smith, of Mount Hope, and of the engineers at Whim Well. But Mr. Blatchford is doubtful about the process, and recommends further official investigation.

At Whim Well the practice begins with 3 to 4 tons of sulphuric acid being diluted and poured over ore in leaching vats containing ore averaging 6% of copper in the form of carbonates and oxides. The object of the leaching vat is twofold. In the first place the ore used is the finer and richer portion of the dump, so the action of the solutions is more rapid and more copper is dissolved. Secondly, the oxygen of the ore acts as a powerful oxidizer to form ferric sulphate. The resulting solutions, on being drawn off, contain free sulphuric acid, copper sulphate (the amount of copper depending on the grade of the ore and length of time of contact), and varying proportions of ferrous and ferric sulphates. The proportion of ferric to ferrous sulphate depends on the amount of oxygen which had been obtained from the air during the time the solutions were percolating through the ore; also as will be pointed out later on, to the amount of oxygen derived from the copper oxides dissolved. It is a good practice to have all the ferrous converted to the ferric state. Assuming this is the case, or nearly so, the solutions are then fit to be passed over pyritic filters to reduce the ferric salts back to the ferrous state, and, at the same time, liberate some portion of the sulphuric acid to aid precipitation of the copper on the scrap iron, and also to prevent the precipitation of iron with the copper, which is the case in the presence of any appreciable amount of ferric sulphate. The pyritic filters mentioned are vats with false porous bottoms, on which is placed the pyritic ore; the flow of the solution is down a pipe and up through the pyritic ore, passing from one vat to another through the series.

In perfect practice all the ferric salts should be reduced to a ferrous state before entering the precipitation vats. If much ferric sulphate is present, there is always the danger of forming basic ferric sulphates, which, though soluble in sulphuric acid, are liable to be discharged from solution when the acidity is reduced below a certain point.

The following equation illustrates the ideal reaction in the pyritic filter :—

$$2FeS_2 + 11\ Fe_2(SO_4)_3 + 12\ H_2O = 24\ FeSO_4 + 12\ H_2SO_4 + S$$

In practice the following are typical analyses of what may be considered fairly normal working solutions when copper is present as chalcopyrite in the sulphide ore :—

	Copper grains per gal.	Ferrous Iron.	Ferric Iron.	Free H_2SO_4.
Entering filter .	20·98	13·32	15·66	6·00
Leaving filter .	39·64	25·10	1·74	20·00

The solutions from the pyritic filter are passed over scrap iron and leave with increased ferrous salts, little, if any, free sulphuric acid, and copper sulphate practically absent. The copper precipitated in the vats forms a precipitate containing about 70% metallic copper. From the precipitating vats the solutions are passed over the big dumps of broken ore in order to dissolve more copper and gain oxygen to convert the ferrous salts back to the ferric state. In the dump sulphuric acid is probably generated to a slight extent by the formation of basic sulphates by hydrolytic action. The solutions leaving the dump should therefore contain more copper sulphate, almost no free sulphuric acid, and a very much increased proportion of ferric sulphate. Before returning the solutions from the dump to the leaching vats the cycle is completed by first passing them through what is known as a converter vat. This vat is deep in proportion to its width, 12 ft. by 10 ft., and is provided with an air-lift and a filter bottom, on which is laid a layer of stones. The air-lift is external and connected to the bottom of the vat from the outside. SO_2 fumes, which are generated by burning sulphur in a closed vessel with air supplied under pressure from an air compressor, are passed down a central tube in the vat to underneath the filter bottom. They, therefore, naturally ascend through the liquid in the vat. The object of the filter bottom and stones is to break up the gas so that it will not concentrate in any particular portion of the solution in the vat, but be uniformly distributed throughout. The chemical action which takes place here is represented as follows :—

$$Fe_2(SO_4)_3 + SO_2 + 2\ H_2O = 2\ FeSO_4 + 2\ H_2SO_4$$

The leaching vats at Whim Well, already described, are three in number, and are calculated to hold 45 tons of ore when full. The dimensions are 20 ft. by 4 ft. Twenty vats 7 ft. by 6 ft. were installed in precipitation, but five of these are now used as pyritic filters, and fifteen only for precipitation. Dump leaching is carried on in a similar method to that in the Rio Tinto process. The top of the dump is divided into small paddocks 10 ft. by 4 ft. in area and the solution is poured into the paddocks in rotation. A constant flow of solution is not effective. What is wanted is an intermittent flooding and drying. A block of the ore, even weighing many pounds, when saturated with solution and allowed to dry soon becomes green on the outside. The copper has been attacked by the acid, and the soluble salts come to the surface by capillary action. Subsequent floodings dissolve and convey these salts away to the precipitation vats. The air-lifts are made of earthenware pipes.

In the dump-leaching a series of paddocks have been top-dressed with pyritic ore to increase the iron sulphates, and when working properly should be a further means for generating sulphuric acid. Owing to the corrosive nature of the solutions and the benefit derived from aëration, pipes are not used, and all liquors are circulated by means of hardwood launders, except the air-lifts, which at present are earthenware.

The process as described and used at Whim Well is based on actual practice at Mount Hope, in New South Wales, where 40,000 tons of waste dump containing 3·2% of copper has been actually treated, the percentage of copper in the dump being reduced to 1%. This work has extended over a period of six years' intermittent treatment. Though the process here has proved an undoubted commercial success, considerable advances in the treatment have since been made by the patentees. It has been found in practice that the original process, though giving the required reactions, was slow, and by adopting certain alterations in the mechanical handling of the material to be treated, the solutions could be made more active, and brought up to a more concentrated form.

The author then gives an account of the practice at Mount Hope. The essential point in the successful working of the Pechey process is the formation of ferric sulphate. To effect this the method of treatment as adopted at Mount Hope is based on the fact that if ferrous sulphate solutions be agitated with sulphur dioxide and air, in the presence of copper oxide, the following action takes place rapidly as follows :—

$$4\,FeSO_4+4\,SO_2+3\,O_2+2\,CuO=2\,Fe_2(SO_4)_3+2\,CuSO_4$$
and $Fe_2\,(SO_4)_3+SO_2+2\,CuO = 2\,CuSO_4+2\,FeSO_4$.

The speeding up of the reaction is due to the presence of the copper oxides in a fine state of division. From a chemical point of view the action is the same as in vat leaching. Water being always present in excess in the event of the copper oxide being insufficient to produce chemical equilibrium in accordance with the foregoing equations, the result would doubtless be as occurs in the converter. $Fe_2(SO_4)_3 + SO_2 + 2\ H_2 = 2\ FeSO_4 + 2\ H_2SO_4$. There is probably always free sulphuric acid in the solution when the process is in operation. The mechanical device to effect the speeding up is as follows : The ore is fine ground and treated in a series of Pachucas, the pulp being agitated with air and SO_2 gas. By adopting the slime treatment in the Pechey process the extraction of the copper is more rapid, the copper is accumulated to a higher percentage in the solutions, which can be more concentrated than in ordinary leaching, precipitation in the scrap iron is more perfect, and the copper cement is higher grade.

The chemical reactions in the process are not quite clear, and the literature on the subject is far from being complete. The treatment being a comparatively recent process, there appears to be much still open for discussion and investigation For instance, the formation of basic sulphates in the solutions when charged with ferric sulphates is in no instance referred to, and as this reaction will be dependent largely on percentages of free sulphuric acid and temperatures, it may have quite an important bearing on the costs and adjustments in the treatment. The class of sulphide ore used in the pyritic filters, control of solution going to the precipitating vats to obtain a high-grade cement, etc., need investigation. Mr. Blatchford has discussed the subject freely with the chemists in the Geological Survey and recommends that they be called in to investigate the points referred to above, as well as any others which may arise.

Gröndal Flotation Process in Germany.—A. Macco, in *Metall und Erz* for May 8 last, gives an account of Gröndal flotation plants in Germany. According to the author most of the experiments in flotation had lapsed into quietude before the war, a quietude from which they were awakened in the endeavour to meet war necessities. In 1918 the Boxbach Company operating near Breidenbach in the Biedenkopf district applied Gröndal machines to the concentration of poor copper ore. This equipment was followed with one of similar machines at Gottesgabe, near Roth, in the same neighbourhood, to recover fahlerz. Later, in January, 1920, the Gröndal flotation equipment erected at the Friedrich-August works, near Nordenheim, for war purposes was put into use by Beer, Sondheimer and Co., of Frankfort, for large-scale experiments upon the Rammelsberg lead-zinc ore. Finally, a fourth Gröndal equipment, begun during the war by the Antweil Co. at its Wilhelm mine in the Upper Ahr valley, and completed with the co-operation of the Stolberg Lead and Zinc Co., was brought into commercial operation.

Of these equipments the position now is that the Boxbach Company, working on a small deposit, has stopped ; Gottesgabe awaits the development of a deeper level ; the equipment at Friedrich-August is temporarily out of commission while certain defects are being made good ; and that at the Wilhelm mine awaits the completion of secondary plant. Though this is not a rosy picture, the author considers the experiences obtained are worth recording.

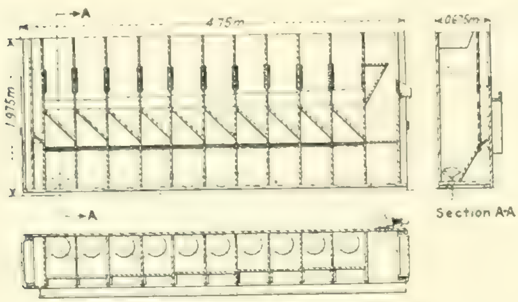
All four plants were worked by froth-flotation brought about by the entry of air from below under pressure. Oil and, exceptionally, chemicals in small amounts were added, the latter partly to assist froth formation and partly to obtain the necessary discriminating surface-tensions. In preparation the ore was reduced in wet ball-mills and tube-mills to about 120 to 200 mesh. The oil, to the extent of about 0·2 to 0·3 kilograms per ton of ore, was added in the tube-mill and the chemicals just before passing into the flotation machine. The consistency of the pulp entering these machines was a normal one for flotation.

Each Gröndal machine consists of a row of agitation boxes with narrow frothing boxes attached in front. In the bottom of each agitation box the air enters through a rose-head of large diameter under pressure sufficient to overcome the column of pulp above, this column being about 3 ft. deep. After agitation the pulp passes out of the agitation box into the frothing box through a slit situated near the top of the pulp column. From the frothing box the froth overflows into a launder over a lip the height of which is adjustable by slats, while the gangue particles sink upon a bottom inclined longitudinally in the direction of the pulp flow, being thereby directed into the next agitation chamber. The cycle then begins afresh.

As will be seen from the illustration the agitation box continues below the frothing box, and it seems likely that sand will collect above the air entry. It is not clear just how the fine division of the air is brought about. Probably the top of the rose-head is made of a porous medium or has holes in it. It is also possible that sand collected over this rose-head may assist in finely dividing the air.

Each agitation box is about 6 ft. high and about

[illegible] and with pyramidal [illegible] about 25 to 30 cu. ft. of free air per minute. In a complete machine [illegible] cells [illegible] in series and the power required for air is about 6 horse-power. [illegible] of one machine [illegible] machines, each [illegible] cells; at Friedrich-August of six machines each of 12 cells; and at Wilhelm of one machine of 12 cells. The capacity of the equipment at Gottesgabe, using only one machine (the other being held in reserve), was about 100 tons per day; that at Friedrich-August, with its six machines all in use, was about the same figure, this lower capacity being due to the fact that Rammelsberg ore carries as much as 50% of sulphides, whereas at Gottesgabe the sulphides amounted to only 6%. The results obtained at Boxbach were: A concentrate assaying 20 to 25% of copper; a tailing assaying 0·1 to 0·15%; and a recovery of 90% from a feed assaying 1·56% of copper. At the Wilhelm mine, where the ore, in addition to chalcypyrite, carried also fahlerz, pyrite, and galena, the recovery of the copper was 90% from a 2% ore. At Gottesgabe,



The Grondal Flotation Cell.

where the ore consisted chiefly of fahlerz with much iron oxide, both containing copper, the concentrate obtained assayed about 30% of copper and 4,000 to 5,000 grams of silver per ton, from a feed which averaged 1·5% of copper and 145 grams of silver; the copper in the iron oxide was not recovered.

At Friedrich-August, treating the complex Rammelsberg lead-zinc ore, the endeavour was to reduce the barite from 37% in the raw ore to about 5% in the concentrate. The following figures represent some of the results obtained:—

	Zn.	Pb.	Ag.	$BaSO_4$.
	%	%	oz.	%
Feed.........	21	11	4·5	37
Concentrate ..	34	21		5
Tailing......	4	2		86
Recovery per cent	87·5	90	90	

The author considers that though in smelting such a lead-zinc concentrate there would be considerable loss, yet in view of the removal of the barite the result might be regarded as satisfactory. In these large-scale tests several thousand tons of ore were treated and the plant is still running. The concentrate is smelted in the company's own smelter, which does not yet receive the foreign ores it did before the war.

Finally, the author is of opinion that the results obtained from this flotation process justify the hope that by it the production of base metals from German ores will be substantially increased and the oppressive dependence upon foreign ores to that extent relieved.

It may be remarked that there is no statement in this article acknowledging that flotation is a process discovered and developed outside Germany. The impression obtained by reading the article is that in the application of flotation Germany is very backward.

Inorganic Origin of Petroleum.—In the *Engineering and Mining Journal* for October 15, Hiram W. Hixon refers to the theory of the inorganic origin of petroleum, of which he is a backer. His remarks arise out of a discussion of a paper by A. G. Wolf on salt-mining in Louisiana, which was published in the issue of the Journal for July 2. Mr. Wolf gave a description of the salt domes of the Gulf Coast, and he said that the origin of these salt domes is an unsettled question, the theories of formation varying from evaporation of sea water to the intrusion of salt in a molten or plastic state.

Mr. Hixon proceeds to elaborate a new theory, as follows: The increase of temperature with depth will, at some depth moderate compared to the earth's diameter, result in a critical temperature for all matter. Thereafter all of the interior mass, below a depth of, say, 200 or 300 miles, will be in a gaseous condition, and denser than the solids that will form out of it. Gravitational compression is the cause of the density, and the conditions of equilibrium make it necessary that the interior mass shall be denser than the crust of solids which rests upon it. All known elements can be volatilized in the electric arc, which is supposed to have a temperature of about 5,000° C. With an increase of 1° C. per 100 ft. of depth, or, say, 50° C. per mile, the temperature of the electric arc would be equalled at a depth of 100 miles.

A critical temperature for any substance is the temperature above which that substance is in a gaseous condition regardless of pressure. Having passed the critical temperature of all matter, the interior mass of the earth is, therefore, in a gaseous state, and by the conditions of equilibrium, is shown to be denser than the solid crust which floats upon it. The crust floats on the gaseous interior for exactly the same reason that ice floats on water; that is, because it expanded when it changed for a gas denser than a solid to a solid, due to secular cooling. This expansion on change of state is the active cause which tears apart the cold crust in long rift cracks and furnishes a path of least resistance for volatile material in the interior to reach the surface. As expansion is in three dimensions, it follows that there should be two sets of such cracks at right angles to each other, and at the intersection of these cracks, which have been called lines of orogenic movement, the salt domes are found. The seal or cap rock is due to some elastic member of the geological section, probably shale, which will stretch under pressure without fracture. The volatile material, consisting of salt, sulphur, and petroleum, and sulphuric gases, comes up along the cracks as the path of least resistance, and being under a rock pressure equal to the depth from which it comes, is capable of making room for itself and doming up any rock mass which will not crack. The alignment of the salt domes, as shown by Mr. Wolf, is characteristic of all the others, and is explainable on the basis of the rift cracks as above described. These rift cracks, rift valleys, and graben are much more numerous than generally supposed. For example, there is a series of them in East Africa,

which is occupied by lakes extending from Lake Nyassa through Lake Tanganyika and the great Rift Valley, the Red Sea, and Dead Sea, over five thousand miles in length. In the United States there is the block faulting of the Great Salt Lake Basin, the basin of Death Valley, Yosemite Valley, and Lake Tahoe, as well as the basin of Lake Superior. The explanation of these dropped blocks is to be found in the slumping down of segments between cracks, or the dropping of wedge-shaped pieces on the sides of rift cracks. The cracks themselves are caused by the expansion of the sub-crustal material in changing from a gaseous state denser than the solid to a solid. Where there is no cap rock which will stretch without fracture, the crack extends through to the surface, and anything of a gaseous nature which comes up the crack escapes into the atmosphere, and is blown about and dissipated. The cap rock or seal above the crack is an all-important condition for the accumulation of the salt, sulphur, and oil in the salt-domes.

The process by which the salt, sulphur, and petroleum are accumulated and condensed is expressible in one word: sublimation. It is well known that salt and sulphur come from the interior and are a part of the material extruded from volcanoes, but it is not so commonly known that petroleum is also of inorganic origin. Illustrating the differences between petroleum and organic oils, whether animal or vegetable, the following list may be studied to some advantage by those who hold that petroleum is of organic origin:

(1) All organic oils, whether animal or vegetable, have both the elements of water, H and O, as a part of their composition. This makes these oils carbohydrates. The oxygen cannot be driven off unless the oil is destroyed by heat. Petroleum, on the other hand, has no oxygen in its composition, and is a mixture of hydrocarbons of the composition expressed by the formula C_nH_{2n+2}.

(2) All organic oils, and organic matter generally, are good fertilizers, and promote plant growth. Petroleum kills all plants, and is used to kill weeds and grass on roads and railways.

(3) Organic oils, both animal and vegetable, have food values for animals and men. Petroleum has no food value, and the lighter hydrocarbons, such as kerosene and gasolene, are poisonous, and are used as insecticides.

(4) All organic oils when boiled with caustic soda and potash yield soap and glycerine. Petroleum does not.

(5) Organic oils when exposed to sun and air become rancid. Petroleum evaporates, but does not become rancid.

These radical differences of composition and properties show plainly a difference of origin. If petroleum were of organic origin, it would undoubtedly have oxygen in its composition, as oxygen is inextricably connected with all processes of organic growth and decay. If petroleum were of organic origin, it would have some of the properties of organic oils, and it has none of them except an oily texture, and other things than oils have that; for example, concentrated sulphuric acid.

To deny the organic origin of petroleum demonstrates nothing; it is essential to the development of a logical theory concerning its genesis, to prove that it can be of inorganic origin.

It was found several years ago that meteorites which were freshly fallen had hydrocarbons of the petroleum type as a part of their composition. Reference to this may be found in Chamberlin and Salisbury's "Geology," in that part which deals with the planetesimal hypothesis. If the earth be conceived to be an aggregation from planetesimals or meteorites, we can at once see why it should have hydrocarbons in its gaseous interior. The hydrocarbons and many other gases would be held there by the power of diffusion, which may have placed them there originally in case the planetesimal hypotheses be not correct. As between the gaseo-molten theory or the planetesimal hypothesis there is no difference as regards the presence in the earth's interior of hydrocarbon and all other gases, including steam, for volcanic action.

Applying the theory of the origin of the salt domes and the inorganic origin of petroleum, as outlined, to the Appalachian oilfields, the following differences arise, due to the absence of "sands" in the Gulf Coast section: The salt, petroleum, and sulphur are confined to the domes or their immediate flanks. In the Appalachian oilfields the rift cracks end in "sands," which are porous and allow the oil, gas, and salt-water to spread out laterally under large areas covered by an impervious blanket seal of shale, which has stretched under the pressure of the overlying rocks and prevented the cracks from extending further upward. The oil and gas spread from the rift crack source laterally, and not up the flanks of the anticlines or toward the centre of a dome, as supposed by the advocates of the organic theory. The anticlines and domes are also the direct result of elevation by reduction of density due to the local accumulation of leavening gases and light material. In fact, the cart has been placed before the horse, and effect has been mistaken for cause. The domes and anticlines are not the cause of the accumulation of oil and gas, but the effect of that accumulation over the rift cracks, which are invisible, but none the less there.

SHORT NOTICES

Mine Ventilation. — At the meeting of the Institution of Mining and Metallurgy held on October 27, Dr. Leonard Hill presented a paper on "Ventilation and Human Efficiency."

Decay of Mine Timbers.—In the *Engineering and Mining Journal* for October 8, Daniel Harrington writes on the decay of mine timber in return air courses, and methods of prevention.

Nordberg Winding Engine. — *Engineering* for October 21 describes and illustrates the Nordberg compound winding engine at the Homestake mine, South Dakota.

Conveyors.—At the meeting of the Newcomen Society, held on October 12, G. F. Zimmer read a paper on the history of continuous conveying devices. An abstract of the paper is given in *The Engineer* for October 14.

Air-Compressor.—*Engineering* for October 14 contains an article describing a 6,400 cu. ft. air-compressor, made for the New Modderfontein gold mine by Belliss & Morcom, Ltd., of Birmingham.

Mine Pumps.—In a paper read before the South Staffordshire and Warwickshire Institute of Mining Engineers held on October 10, S. H. Cashmore gave particulars of the Feuerheerd pump for use in mines.

Mine Sampling.—In the *Engineering and Mining Journal* for October 1, B. G. Anderson describes the sampling method employed at the disseminated copper deposits at Tyrone, New Mexico, belonging to the Phelps Dodge Corporation.

Dredging Efficiencies.—In the *Engineering and Mining Journal* for October 22, C. W. Gardner contributes an article on drilling results and dredging returns.

Prospecting.—In *Economic Geology* for August, Augustus Locke writes philosophically on "ore-finding."

Copper Leaching.—In the *Mining and Scientific Press* for October 15, Joseph Irving describes the copper-precipitation process and plant at Copper Canyon, Nevada.

Zinc Smelting.—In the *Engineering and Mining Journal* for September 10, Evans W. Buskett wrote on the smelting of zinc ores in a blast-furnace under pressure. In the issue of October 15, B. M. O'Hara gives a bibliography of the subject, showing that previous experiments had shown the idea to be incapable of application.

Ferro-Vanadium.—The *Journal of Industrial and Engineering Chemistry* for October contains a paper by G. L. Kelley and others on the determination of vanadium and chromium in ferro-vanadium by electrometric titration.

Archæan Sulphides of Sweden and Finland.—In *Economic Geology* for August, Per Geijer writes on the Archæan sulphide ores of Sweden and Finland, noting particularly the Orijarvi district in South-west Finland. The term Fenno-Scandia has recently been proposed for the geological region comprising the Scandinavian peninsula and Finland.

Gold Deposits in British Guiana.—In a paper presented at the meeting of the Institution of Mining and Metallurgy held on October 27, J. N. Justice described the geology of a gold deposit on Eagle Mountain in British Guiana, near the confluence of the Potari and Essequibo Rivers.

Bolivian Tungsten. — The *Engineering and Mining Journal* for September 24 reprints a paper by F. L. Hess, presented at a meeting of the Society of Economic Geologists, describing tungsten deposits in Bolivia.

Tin in China.—At the meeting of the Institution of Marine Engineers held on October 11, W. Semple read a paper on the mining and treatment of tin ore in Kotchiu, Yunnan.

Almaden Quicksilver Mine. — In *Economic Geology* for August, Courtenay De Kalb describes the Almaden quicksilver mine, Spain, and F. L. Ransome writes on the ore of this mine.

Borax in Nevada.—In the *Engineering and Mining Journal* for October 1, Hoyt S. Gale describes the newly discovered colemanite deposit at Callville Wash, Clark County, Nevada.

Oil in Guatemala. — In the *Engineering and Mining Journal* for October 1, A. H. Redfield discusses the possibilities of finding petroleum in Guatemala.

Oilfield Losses.—At the meeting of the Institution of Petroleum Technologists held on November 8, A. Beeby Thompson read a paper on the Elimination of Oilfield Losses.

W. J. Loring.—The *Engineering and Mining Journal* for October 15 gives a biographical sketch of W. J. Loring.

L. D. Ricketts. — The *Mining and Scientific Press* for October 1 contains an account of an interview with Dr. L. D. Ricketts, written by T. A. Rickard. Dr. Ricketts is known in connection with his mining and metallurgical work at copper mines in Arizona and Sonora.

RECENT PATENTS PUBLISHED

☞ *A copy of the specification of any of the patents mentioned in this column can be obtained by sending 1s. to the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. 2, with a note of the number and year of the patent.*

7,663 of 1920 (169,188). Scovill Manufacturing Co., Newhaven, Connecticut. Electric melting furnace for copper and other non-ferrous metals.

8,359 of 1920 (168,927). E. Edser and L. A. Wood, London. A process for the concentration of ores, particularly those containing cassiterite or wolfram together with colloidal metallic oxides, such as those of iron and aluminium, which consists in mixing the finely pulverized ore with water, preferably soft water, adding a deflocculating agent, such as sodium silicate or silicic acid salt, thus freeing the particles from one another so that certain ore particles will sink, while the said colloidal particles remain in suspension, removing the suspension from the settled product and subjecting the latter to treatment by a flotation process.

12,368 of 1920 (168,627). A. H. Eustis, Norfolk, Massachusetts. Improvements in the method of removing sulphurous acid from smelter smoke by dissolving in water and afterwards recovering by the action of heat and vacuum.

14,800 of 1920 (144,278). United Filters Corporation and E. J. Sweetland, New York. Improvements in the construction of pressure filters of the leaf type.

14,885 of 1920 (146,939) and 15,732 of 1920 (146,942). W. E. Trent, Washington. In the smelting of ores, introducing them into the furnace in a fine state of division together with reducing gases, and introducing at the same time jets of water to be used partly for controlling the temperature, and partly as a reagent; also methods of collecting the products of reaction.

14,944 of 1920 (168,643). P. Danckwardt, Denver. Method of producing anhydrous aluminium chloride, particularly for recovering this compound used in the production of petrol from mineral oils.

15,121 of 1920 (144,306). American Smelting and Refining Co., New York, and G. C. Howard, Tacoma. Method of producing elemental sulphur from sulphurous acid recovered from smelter smoke by passing the acid gas mixed with air through incandescent coke.

15,122 of 1920 (168,420). American Smelting and Refining Co., New York. Machine for stacking bars and slabs of metal coming from the casting machines.

15,356 of 1920 (168,429). A. R. Mangnall, Chester. Improvements in the inventor's machine for boring through soft earth without removing the earth.

15,519 of 1920 (168,434). J. W. Moffatt and W. F. Sutherland, Toronto. Furnace for reducing metals from oxide without fusion, and subsequently melting the product electrically.

15,646 of 1920 (168,977). W. C. Heraeus Co., Hanau, Germany. Method of securing purity and regularity of characteristics of certain metals

used in the manufacture of thermo-couples for pyrometers.

16,017 of 1920 (167,917). J. ADAIR, Taunton. Construction of heated chambers for drying china clay.

16,461 of 1920 (145,431). ANSCHÜTZ & Co., Kiel. Method of keeping vertical bore-holes in true alignment.

16,495 of 1920 (145,433). W. BREIL, Essen. Method of constructing concrete shaft-linings which will be water-tight.

16,586 of 1920 (169,247). E. E. NAEF, Nottingham. For the production of metallic nickel and nickel salts, the treatment of finely divided nickel sulphides with solid caustic alkalies, or mixtures thereof with any or all of the following substances: Sodium carbonate, common salt, sodium sulphate, sodium sulphide, calcium oxide and hydroxide, at fairly low temperatures, 250° to 600° C.; with or without the addition of finely divided coal, and in presence or absence of hydrogen or gases containing such, or in presence of both coal and hydrogen.

17,092 of 1920 (169,288). E. W. WILKINSON, New York, and MINERALS SEPARATION, LTD., London. Method of producing frothing agents suitable for the flotation process by subjecting certain organic substances such as kerosene, to a partially decomposing heat in the presence of air.

17,765 of 1920 (169,301). HOYANGSFALDENE NORSK ALUMINIUM CO., Christiania. Process of producing alumina from clay, characterized by the combination of the operations of decomposing a potash-bearing clay with sulphuric acid, lixiviating the decomposition product, precipitating potash alum from the solution, decomposing the potash alum by heating, whereby potassium sulphate and alumina are obtained, separating the potassium sulphate from the alumina by lixiviation, recovering potassium sulphate from the solution, and adding a portion of the potassium sulphate to a sulphate solution obtained by decomposition of a further portion of potash-bearing clay.

18,179 of 1920 (145,789). G. BONNARD, Plombiere St. Michel, Savoy, France. Process for refining tin and antimony by the action of dry chlorine on the crude metal, so obtaining anhydrous liquid chlorides.

18,398 of 1920 (146,410). C. CLERC and A. NIHOUL, Paris. Manufacture of pure zinc sulphide by the action of hydrogen sulphide upon a slightly acid solution of a zinc salt with addition of magnesia or an appropriate magnesium salt such as magnesium carbonate in such proportions as to allow a small proportion of acid to remain free in the solution at the end of the operation.

19,159 of 1920 (168,479). G. R. BROWN, Sydney. Machine for electrostatically separating finely divided ores.

19,956 of 1920 (147,903). METALLBANK UND METALLURGISCHE GESELLSCHAFT, Frankfort. Use of lithium for alloying with aluminium to increase its mechanical strength.

20,023 of 1920 (148,122). L. HACKSPILL and C. STACKLING, Strasbourg. Manufacture of sodium and other alkali metals by the reaction between the chloride of the metal and calcium carbide, conducted dry under considerable heat.

20,170 of 1920 (148,242). CHEMISCHE FABRIK RHENANIA and G. A. VOERKELIUS, Stolberg. Compound fertilizer made by the action on phosphate of nitric acid and potassium sulphate.

21,033 of 1920 (149,247). J. SIMON, Frankfort. A process for the chloridizing-roasting of burnt pyrites, wherein the material, mixed with salt and with less than 2% of coke breeze, is roasted on the counter-current principle in an air-tight stationery shaft, by means of air under pressure passing upwards through the apparatus, while the completely roasted material is mechanically removed.

21,921 of 1920 (168,497). J. & E. WRIGHT, LTD., and J. W. A. RULE, Birmingham. A pocket clinometer and caliper gauge combined, suitable for measuring the inclination of ropes, their diameter, and the depth of pulley grooves.

26,091 of 1920 (168,781). F. PRATT, Treherbert, Glamorgan. A safety device for automatically applying the brake to winding engines.

27,132 of 1920 (168,731). W. H. BOORNE, London. Furnace for oxidizing tin.

29,215 of 1920 (153,297). FARBENFABRIKEN F. BAYER, Cologne. Precipitating sulphur from sulphuretted hydrogen by mixing with air and precipitating on porous carbon.

NEW BOOKS, PAMPHLETS, Etc.

☞ Copies of the books, etc., mentioned below can be obtained through the Technical Bookshop of *The Mining Magazine*, 724, Salisbury House, London Wall, E.C. 2.

Some Principles Governing the Production of Oil Wells. By CARL H. BEAL and J. O. LEWIS. Bulletin 194, published by United States Bureau of Mines.

Underground Conditions in Oilfields. By A. W. AMBROSE. Bulletin 195, published by the United States Bureau of Mines.

Silver Ores. By H. B. CRONSHAW. Paper covers, 152 pages. Price 6s. net. Prepared under the direction of the Mineral Resources Committee of the Imperial Institute. London: John Murray.

Petroleum. Paper covers, 110 pages. Price 5s. net. Prepared under the direction of the Mineral Resources Committee of the Imperial Institute, jointly with His Majesty's Petroleum Department, with the co-operation of H. B. Cronshaw. London: John Murray.

Detection and Estimation of Platinum in Ores. By C. W. DAVIS. Technical paper 270, published by the United States Bureau of Mines.

Flotation Tests of Idaho Lead-Zinc Ores. By C. A. WRIGHT, J. G. PARMELEE, and J. T. NORTON. Bulletin 205, published by the United States Bureau of Mines.

Mica, Bauxite, Borax, Corundum, and Garnet. By Dr. J. COGGIN BROWN. Being Bulletins 12 and 15 on Indian Industries and Labour, issued by the Government of India. London: India Government's Department of Commerce and Industry, 60, Winchester House, E.C. 2.

Geology of the Diamond-bearing Gravels of the Somabula Forest. By A. M. MACGREGOR. Bulletin 8 of the Geological Survey of Southern Rhodesia.

COMPANY REPORTS

Chenderiang Tin Dredging.—This company was formed by Bright & Galbraith, Ltd., in 1914, to acquire alluvial tin ground in Chenderiang Valley, Perak, Federated Malay States. A bucket-dredge started work in April, 1915. The report for the year ended March 31 last shows that the dredge treated 965,000 cu. yd. of ground and extracted 339 tons of tin concentrate, the yield averaging 0·79 lb. per yard. The output from the hydraulic

[illegible] and from tributers was 104 tons, so that the total output was 443 tons. The company's income was £50,406, and the net profit was £5,251, out of which £3,727 has been applied to the extinction of the balance of the development account.

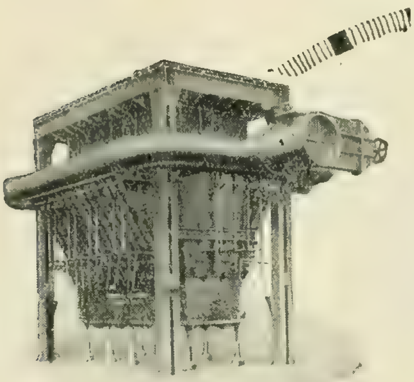
Ipoh Tin Dredging. This company was formed in 1913 to acquire alluvial tin property at Lahat, in the Kinta Valley, Perak, Federated Malay States. A bucket-dredge started work in August, 1915, and two more dredges were ordered later. The company is controlled by the Borneo Company, Ltd., and L. G. Attenborough is the manager. The report now issued covers the fifteen months ended March 31 last. During this time 656,700 cu. yd. of ground was treated, for a production of 215 tons of tin concentrate, being a yield of 0·73 lb. per yard. The amount of ground treated was below normal, owing to the limestone pinnacles being high and also owing to the inefficiency of the pumps. On the other hand the yield per yard was considerably higher than during 1919. The accounts show an income of £37,036 from the sale of tin concentrate, and an adverse balance of £1,429. Further information is given in the Review of Mining.

Consolidated Gold Fields of New Zealand.—This company was formed in 1896 to acquire from the late David Ziman certain gold-mining properties in the Reefton district of New Zealand. The company floated off the Progress and Blackwater properties as separate companies, and continued to work the Wealth of Nations mines itself. The Wealth of Nations was closed in 1918, owing to a fire. The report for the year 1920 shows that the mine has been drained and partly repaired, but that a resumption of operations is not yet possible. The ore reserve remains as reported at the end of 1919, namely 16,044 tons, averaging 11·58 dwt. gold per ton. The accounts show a loss of £12,108 for the year. As the year commenced with a credit balance of £19,476, the year ends with a credit balance of £7,368. **Progress Mines.**—Mining operations were suspended at the end of August, 1920, as the results of development above the 11th level were not promising. When economic conditions allow, it is intended to sink deeper. During the eight months from January to August, 1920, the amount of ore raised was 8,102 tons, from which gold worth £12,619 was extracted. The working cost was £15,509, leaving a working loss of £2,889. **Blackwater Mines.**—The amount of ore treated during the year was 24,468 tons, yielding gold worth £58,607 The working cost was £45,317, leaving a working profit of £13,290. Development continues to give satisfactory results, and at the end of the year the reserve was estimated at 86,600 tons, averaging 8·47 dwt. per ton.

Broken Hill South.—This company was formed in 1893 to work silver-lead-zinc deposits at the south end of the Broken Hill range, New South Wales. Operations were suspended from April, 1919, to November, 1920, on account of labour troubles. In July, 1919, a large part of the surface plant was destroyed by fire, and the time from then until the end of the strike was occupied in the work of reconstruction. The report now issued covers the year ended June 30 last. This records that the flotation plant treating dump slime was restarted on November 15, 1920, mining operations resumed on December 20, and one section of the reconstructed concentrating plant put to work on January 24, 1921. On January 25 the smelting plant of the Broken Hill Associated Smelters at Port Pirie suffered serious damage by fire, so it was not possible to send the lead concentrates thither for treatment. The Sulphide Corporation, however, undertook to treat a limited amount of these concentrates, along with similar concentrates from other mines, at the Cockle Creek smelters. From March 2 to 29 operations ceased at the mine and mill on account of coal shortage, but from the latter date operations have been continued on the basis of half-time one-shift per day. During the period covered by the report, 37,923 tons of ore was raised from the mine and sent to the concentrators, where the following products were obtained: 5,981 tons of lead concentrate averaging 63·4% lead, 8·6% zinc, and 27·3 oz. silver per ton; 24,667 tons of zinc tailing, averaging 17·3% zinc, 3·6% lead, and 4·3 oz. silver; and 5,682 tons of slime averaging 13·2% lead, 14% zinc, and 10·3 oz. silver. The current slime was treated for lead, producing 1,027 tons of concentrate, averaging 54·7% lead, 10·9% zinc, and 45·6 oz. silver; the zincy residue averaging 14·7% zinc, 4% lead, and 2·6 oz. silver. There was also treated 54,864 tons of dump slime, averaging 11% lead, 13·4% zinc, and 7·9 oz. silver, for a yield of 7,299 tons of lead concentrate averaging 47·2% lead, 15·1% zinc, and 41·2 oz. silver; the zincy residue averaging 13·2% zinc, 5·4% lead, and 2·7 oz. silver. The zinc tailing (other than slime) obtained from the treatment of the crude ore, 24,667 tons (as before mentioned), was delivered to the Amalgamated Zinc (De Bavay's), and 158,908 tons of dump tailing, averaging 16·9% zinc, 6% lead, and 3·9 oz. silver, was delivered to the Zinc Corporation. The accounts show a loss of £56,701, and in addition £55,207 was written off for depreciation of plant, and £13,333 was allowed for debenture redemption, provision for these two items coming from the reserve fund. The ore reserve remains at 3,500,000 tons, as no great amount of development has been possible lately.

North Anantapur Gold Mines.—This company was formed in 1908 by John Taylor & Sons, as a subsidiary of the Anantapur Gold Field, Ltd., for the purpose of working old gold mines in Madras Presidency, India. Milling commenced in 1910. Additional capital was raised in 1911 by the issue of preference shares for the purpose of increasing development. The scale of operations and profits was never large. Four years ago developments began to give poor results, and the output has decreased ever since. The report for the year ended June 30 last shows that 8,800 tons of ore was raised and treated in the stamp-mill for a yield of 9,977 oz., and that 9,800 tons of sand and slime yielded 965 oz. In addition 357 oz. was obtained by re-treatment of dump material, bringing the total yield to 11,299 oz. This gold was sold for £61,823, of which about £13,000 represented premium. The working profit was £30,354, out of which £14,374 has been distributed as dividend, being at the rate of 27½% on the £25,000 preference shares, and 7½% on the £91,253 ordinary shares. Mining operations during the year have not resulted in the discovery of any further ore-bodies of value and the reserve at June 30 was only 7,000 tons. There remains 40,000 tons of sand on the dump to be re-treated. In all probability mining operations will have to cease shortly. The company has interests in copper deposits in the Chota Nagpur district, which are now being investigated.

Mining Machinery



Fraser & Chalmers
Water Jacketted
Blast Furnace.

SMELTING.

Fraser & Chalmers Engineering Works were among the pioneers of modern water-jacket blast furnace and converter construction. Their experience extends upwards of 40 years, and they have been closely associated with the improvements that have taken place in design and construction of smelting and bessemerizing plant during that period.

Mechanical Roasting Furnaces, Sintering Pots, Reverberatory Smelting and Refining Furnaces, Tin Smelting Plant, Lead desilvering and Refining Plant, Faber du Faur Retorting Furnaces, etc.

"RAPID" ELECTRO-MAGNETIC ORE SEPARATOR

(Thompson-Davies Patent)

We will guarantee our Type "O" Separator to give equal efficiency, as a minimum, to the German Apparatus.

SIMPLE IN OPERATION.

ALL TUNING UP MAY BE DONE WHILST MACHINE IS WORKING.

NO FLIMSY CROSS BELTS.

AN ABSOLUTE MINIMUM OF DUST.

EVERY PART IS EASILY ACCESSIBLE.

SEPARATING MAGNETS CAN BE SET FINER THAN ANY OTHER MACHINE ON THE MARKET.

For the separation of feebly magnetic ores:—Wolfram-tin, Wolfram-bismuth, Monazite Sands, Siderite from Zinc Blende, etc., and Ores consisting of particles of different magnetic permeability.

We shall be pleased to demonstrate a Machine at work, preferably on inquirers' own samples.

Inquiries should be accompanied by information as to quantity to be treated per hour, as several sizes are listed, and the capacity varies according to the Ore.

Beware of exaggerated statements as to output of other makes.

For controlling and elevating the discharge from DORR THICKENERS. Simple to operate and requires very little power.

As used in the Dorr System of Continuous Countercurrent Decantation.

Is in successful operation in many different types of metallurgical and chemical plants for handling both dilute and thick sludges.

Memorials to the Dead 330

Particulars are given of the two Memorials erected by the Institution of Mining and Metallurgy and the Institution of Mining Engineers, respectively, in the honour of their members who fell in the Great War, with an account of the ceremony of unveiling performed by Earl Haig.

The Huelva Rocks and Ores........ 332

A paper on this subject was read by Mr. Henry F. Collins before the Institution of Mining and Metallurgy at the November meeting. The editor gives an outline of Mr. Collins's suggestions with regard to the processes of enrichment of the pyrites.

The Rhodesia Broken Hill Fossils... 333

Brief mention is made of the animal remains found in the limestone caves at Rhodesia Broken Hill, in particular of the prehistoric human skull.

James Wickett 334

The editor records his appreciation of the beneficent life of the Redruth stockbroker who did so much for Cornish and Malayan mining.

REVIEW OF MINING 335

ARTICLES

Mining Possibilities in Burma....... .... *Harry D. Griffiths* 339

The author shows that the mineral resources of Burma are not fully appreciated by the general public, and presents evidence that there are many opportunities for profitable ventures, particularly in connexion with gold-dredging.

Ventilation and Working Efficiency.. .... *Bernard W. Holman* 350

The author discusses the modern principles of ventilation and working conditions as applied to hot and deep mining.

Memorials to the Dead

On November 24, Field-Marshal Earl Haig unveiled the Memorials erected in the honour of the members, associates, and students of the Institution of Mining and Metallurgy, and of the members of the Institution of Mining Engineers who fell in the Great War.

After brief introductory remarks by Mr. F. W. Harbord, president of the Institution of Mining and Metallurgy, and by Colonel W. C. Blackett, president of the Institution of Mining Engineers, Earl Haig said :—

" Two good reasons urged me to accept your invitation to come here to-day to unveil these two Memorials to your gallant dead.

" The first, and more general one, is that on all such occasions I am able to pay personal tribute to a section of those many thousands of brave men who fought under my command in France, and under my command paid the last and greatest sacrifice that love of King and Country can demand of true and loyal citizens.

" The least that I can do, I, who acting myself in the execution of my duty, asked and obtained so much from them in the execution of theirs, is to join with those who knew and loved them in honouring their names.

" My second and more particular reason for wishing to come here is that you afford me the opportunity to say a few words of especial thanks to a body of men whose work in France seldom drew upon itself much notice or glory at the time ; but was surpassed by none in the demands it made upon the skill, courage, and resolution of the individual concerned or in the service it rendered to the Army as a whole.

" One thinks naturally of the battle of Messines, and of the mighty series of explosions that tore great gaps in the German line on June 7, 1917, and gave the signal for one of our most successful attacks. That was the work of the special services to which you sent so many gallant men ; and it was indeed a signal triumph of British mining in war. Yet few, I think, outside those who took part in the work or saw and benefited by its results, realize the immense amount of steady and persistent toil, in every circumstance of peril, surrounded by danger in a form that might well appal the stoutest-hearted, that went to the preparation of that triumph. Few, I know, realize how vast and how important to the safety, comfort, and success of our troops, was the other work of our miners ; work that was little commented upon in the Press, but yet went on steadily and continuously day after day and year after year all along the British front.

THE MEMORIAL ERECTED BY THE INSTITUTION OF MINING ENGINEERS.

" There was no truce at any time to the warfare that went on underground ; no respite from the toil that the needs of the Army imposed upon those who were the masters

of the art of digging underground. Only, there were periods of redoubled activity, or more than common strain. Every offensive undertaken by us, right up to the days of the last great series of advances, meant a fresh call upon the energy, industry, and courage of these special services upon whom the due preparation of those offensives so largely depended. Tunnelled approaches had to be constructed for great distances, dug-outs built for headquarters, dressing-stations, and shelter generally. Every big offensive made demands of this kind. An immense amount of work was done for the Somme. The preparations for the battle of Arras attracted little attention compared with those for the Messines battle, but were no less valuable. Then, later, when the day of the elaborately mounted attack was over, the tunnelling companies found a new work, hardly less arduous or dangerous, in the discovery and removal of many thousands of German mines.

"I am talking to those who themselves know something of these things; but it is right that others should know, too, and here where you are met to pay a last honour to comrades, members of your Institutions who actually accomplished these things and died nobly in the doing of them, I am glad to thank anew—not for myself only, but on behalf of the whole Army—a most gallant body of men.

"This is an occasion for deep sympathy with those who have lost so much and see in these memorials the commemoration of their private sorrow. It is an occasion, too, for admiration and gratitude towards men who gave so much, all that men could give, for the liberty and honour of their fellow-countrymen. It is more even than that. It is an occasion for us who remain to take courage from the example of those who have so bravely gone before us. The cause for which these honoured dead gave the last full measure of their devotion is still ours to uphold. The task to which they gave their lives is laid upon us and our children to complete.

"Therefore as days go by we should look upon these memorials with quiet sorrow, but with lasting pride. They should be to us lessons not only of what men have done, but of what true men can do. Then shall we and generations to come after us draw hope and inspiration from the memory of what these men accomplished in the strength of their faith and patriotism. So that in the days of difficulty, now and hereafter, the great commonwealth of nations to which we all belong, which we all love, shall never lack for men who will—as did these whose names are here written—count their own lives as nothing in their country's service."

THE MEMORIAL ERECTED BY THE INSTITUTION OF MINING AND METALLURGY.

The Memorials are installed in the library of the new house of the two institutions in City Road. That of the Institution of Mining Engineers consists of a mural plaque of marble, on which is a draped female figure in bronze. Underneath is a bronze plate bearing the dedicatory inscription, and on the marble are carved the names of the fallen. The rising sun about the base of the figure is done in gold mosaic. The sculptor was

Mr. Allan G. Wyon. The Memorial erected by the Institution of Mining and Metallurgy was designed and executed by Lieut.-Col. Peter N. Nissen, a member of council of the Institution. Colonel Nissen's idea was to portray the work done by the tunnellers, and the main figure represents a second-lieutenant in the act of exploding a mine. For the purpose of description of this memorial we cannot do better than quote some verses written by a visitor who was present at the unveiling ceremony.

THE MEMORIAL
erected by the
INSTITUTION OF MINING AND METALLURGY
TO THEIR GLORIOUS DEAD.

Would they, the brave ones early dead and gone,
Desire that we should carve their names in stone,
Erect memorials in their honour, and
Inscribe their deeds upon the roll of fame ?
With humble self-effacement they might say
That they did not regret the sacrifice,
They only fought for duty, not for praise,
That those who fought and lived deserve
An equal recognition ; or they might
Prefer the glory to be given to Him
Who sent them strength and heart to lay the foe
And so preserve the freedom of the world.
Thus is the monument designed to show
The work the miners did throughout the war,
That both their friends and those who follow on
Shall look on it with thankfulness and pride.
To render glory unto God we need
No sculptured figure with symbolic aim ;
Sufficient is the record of good deeds,
Portrayed by deft and reverential hands.
But best of all to please both dead and quick
Is that the monument should be designed
By one who was himself upon the field
And could present the actual scenes of war.
High on a pedestal of malachite
Stands a young officer of engineers,
With strained attention ready to explode
The charge and force the climax of attack ;
The boots, the mud, the sand-bags, and the tins
Show the environment in which he worked.
The sculptor has recorded other scenes,
Familiar to the miner in the war,
In bas-relief in panels 'neath the plinth ;
Field and machine guns, scouting aeroplanes,
A Flanders road with all its trees destroyed,
A bridge to span a Belgian waterway,
A tunneller listening with the geophone,
A warship, and a poison chemist's den ;
The habitations on the firing line
In which the men took cover or sought rest :
The unseen hut, the dug-out, and the house
Battered by shell and falling to the ground.
On silver plates are cut the names of those
Who died, with glowing words of true regret.
The bronze, the malachite, the silver, all
Suggest the missions of the fallen men
Before the battle called them to the front.
Complete it stands upon a base of oak,
Oak, British oak, that still denotes the strength
And steadfastness of Britain's sons.
Farewell ! Yet not farewell, ye noble dead,
Your name shall surely live for evermore !

The Huelva Rocks and Ores

The paper read by Mr. Henry F. Collins before the Institution of Mining and Metallurgy on November 17, entitled "The Igneous Rocks of the Province of Huelva and the Genesis of the Pyritic Ore-bodies," is an important contribution to the study of the economic geology of that celebrated mineral region. The problem of unravelling the nature and sequence of the great variety of igneous rocks found there and the origin of the ore deposits has never received the attention of the mining companies working in the South of Spain in the way it deserved. The reason for this neglect is to be found in the fact that the ore-bodies are too large and continuous to require the aid of science in their discovery. It was rather the problem of dealing with the ores, from the standpoint of the metal and chemical industries, that called for close study of the companies. In other words, it was the destination, not the origin, of the ores that absorbed attention. The chief literature on the subject hitherto published has come from Spanish, German, Swedish, and French geologists, of whom Gonzalo Tarin, Vogt, and Klockmann are the best known ; and in the early days the only contributions of note coming from an Englishman were those by the late Mr. J. H. Collins, father of the present author. Some of these writers took the view that the deposits were of sedimentary origin contemporaneous with the enclosing slates ; others that they were formed by magmatic segregation from the igneous rocks ; while the Spanish and French geologists mostly adhered to the view that they were in the main vein deposits formed by ascending solutions. Of geologists with more modern ideas who have visited Huelva province, the first to write a convincing account of the rocks and ores was the late Dr. A. M. Finlayson, then a student at the Royal School of Mines. Finlayson was a young New Zealander, and he undertook, while at South Kensington, the petrographic study of a number of mineral districts for the purpose of winning his D.Sc. of London. It is a remarkable circumstance that he should have grasped the meaning of the Huelva rocks and ores in so short a time, and that so young a man should write a paper that almost immediately was accepted as a classic. His untimely death early in the war was regretted by all who knew him, for it is clear that mining geology thus lost one who promised to become

an exponent of the highest rank. His work at Huelva was confined to only one part of the mineral zone, and some of his conclusions, of minor importance, were based on incomplete data; but in spite of this drawback his exposition of the geology of the district is nowadays universally taken as a convenient basis for the study of these rocks and ores.

The paper written by Mr. Henry F. Collins represents the results of his detailed investigations during the eight years of his management of the Huelva Copper and Sulphur Company's group of mines. His intention was to prepare a geological map of the whole mineral province, but his limited leisure during mine management and the extraordinary complexity of the rocks combined to make it impossible for him to complete his task before leaving Spain. He had, however, collected a vast amount of evidence which enabled him to draw certain conclusions with regard to the nature of the rocks, and the history of the ore-bodies. This evidence and his arguments based thereon form the substance of the present paper. Extracts from the paper are given in the Mining Digest elsewhere in this issue.

Mr. Collins's evidence generally confirms Finlayson's main conclusions, but in some cases his new evidence tends to modify them in detail. He entirely confirms Finlayson's conclusions as to the origin of the ore: "The ore-bodies are in the main replacements of zones of rock, which, owing to crushing and shearing, or to other causes, was specially permeable to the passage of mineralizing solutions." Mr. Collins adds to this general conclusion that the ore-bodies are sometimes replacements, not merely of the crushed and sheared zones of a particular rock, but also of narrow residual belts of slate or schist that had become enclosed between two similar or dissimilar dykes of igneous rock; and that replacement has occurred in many instances at a contact between slate or schist and igneous rock; moreover, that there is plenty of evidence of the gradual replacement of rock by ore, particularly in the schists, where the banded structure is still preserved.

An interesting part of the paper is that in which Mr. Collins advances theories to account for the various enrichments of copper in the pyrites, in addition to the theory of secondary enrichment already well known. As the enrichments referred to by Mr. Collins took place during the formation of the deposits or shortly afterwards, he calls them "primary" enrichments. He divides them into two classes, those coming from deep-seated sources, and those coming in laterally. As regards the former, he holds that, as the circulation of the mineralizing solutions became less violent owing to cooling and to the local cessation of earth movement, the solutions became relatively more highly charged with copper than with iron, and produced local primary impregnation in the pyrites already deposited. As to the latter, he believes that an enrichment with chalcopyrite has in many cases been effected through the infiltration of solutions laterally from the dykes of diabase and porphyry which so frequently run parallel to the lodes at a short distance from them. These theories, especially the latter, have helped in locating the parts of the ore deposits richest in copper, and therefore deserve serious consideration.

There are one or two other points in connexion with Mr. Collins's paper to which attention may be drawn. One is his implied protest against the recommended abandonment of the term "diabase" by the committee of British petrographers. A second is the author's analysis of the rocks for pyrites and chalcopyrite, which shows the remarkably regular presence of these minerals throughout the igneous rocks and slates. The full significance of the condition thus revealed is by no means clear; at any rate, it is on a par with the results obtained by Lincoln and others that gold and silver are to be found in all igneous rocks. It would appear to confirm Mr. Collins's theory of lateral primary enrichment. A third item of note is the author's statement that throughout the various igneous masses signs of contact metamorphism are by no means plentiful. This revives the query that has often been given a place in our pages as to the possibility of molten matter passing through solid rock without affecting its surface in any way; but this is too big a subject to broach on this occasion.

Rhodesia Broken Hill Fossils

The Rhodesia Broken Hill mine is not only noted for its ores containing lead, zinc, and vanadium, but it has provided many interesting studies for the zoologist owing to the immense collection of animal remains found in the caves. Some years ago Messrs. Franklin White and F. P. Mennell wrote of the discoveries here. Cave-hunting

provides the romance of geological study, and in this country the limestones of Yorkshire and Durham have become famous in this connexion. At Rhodesia Broken Hill the caves have yielded fossils for years, and many of these have been sent to the Natural History Museum at South Kensington, but hitherto the bones discovered have been the remains of animals closely related to those that now live in the district. The importance of these caves has jumped suddenly to the front by the discovery of a skull of a prehistoric man. This was uncovered by Mr. W. E. Barren, a member of the staff of the company, and it was brought to London by Mr. Ross Macartney, the manager. It now lies at the Natural History Museum, where it is attracting the attention of the zoological savants. Communications relating to its antiquity have appeared in the *Times* and *Nature*, emanating from Dr. Smith Woodward, Dr. Elliott Smith, Sir E. Ray Lankester, Sir Arthur Keith, and others. These authorities agree that the skull belonged to a being combining human and ape-like characteristics, but far nearer to any modern type of man than to the ape. Comparisons are made between this skull and those discovered at Piltdown, in Java, in South Africa, and in the caves of Belgium and France, and as far as can be gathered the judgment is that the Rhodesian skull belongs to a new type and is perhaps later than the others named.

James Wickett

The late Mr. James Wickett, who died at his home at Redruth on November 12, at the the age of 79, was one of the best friends of metalliferous mining that ever lived, from the points of view alike of the professional man, the miner, and the investor. He never claimed to be brilliant and never aspired to be smart, but he had a sound knowledge of the business of mining, and a conscientious and altruistic method of dealing with the three classes of people connected with this industry. He was always an optimist, but never allowed his natural inclination to believe in and hope for the best to bias his judgment. The object of his investments in mining was to reap a reward in the way of dividends earned by extracting metals from the ground, not to seek to create a boom in his shares and unload on his clients and the public; and all his recommendations as regards purchases of shares were based on the same lines. His clients looked for the profits out of dividends and from the capital appreciation of their holdings arising solely from the intrinsic worth of the mines. He had no parent financial company to float and control his Malayan group of tin mines, so that shareholders were not saddled with big promotion and agency expenses and commissions, and the market for the shares in the mining companies was free and not influenced by the Stock Exchange requirements of such a parent company. The working costs at the mines were always kept within reasonable limits, and the charges for administration at the home offices were, we almost might say, ridiculously low. In this policy he was well backed by the engineers, with whom he was so long associated.

At the meetings of the companies of which he was chairman he many a time gave reminiscences of his early experiences. He used to tell how his father made money out of Tincroft in its palmy days, and that he was indebted for his liberal education to the funds thus made available. Then he told of his first business engagement with Mr. J. M. Williams, of Gwennap, and of his position as confidential agent with Williams, Foster & Co., of Swansea. For forty-two years, up to the time of his death, he conducted a stockbrokers' business at Redruth, most of the time being associated with Mr. Samuel Abbott, and latterly with his sons, Mr. Tom Wickett and Mr. Stanley Wickett.

It is about thirty years since the firm of Osborne & Chappel, of Ipoh, Perak, approached him with the view of obtaining capital to increase the development of the property now so well known as the Gopeng. After careful study and inquiry he and his friends subscribed the £5,000 required, and thus laid the foundation of a business that has had many and varied beneficent influences in mining circles, both in this country and the Malay Peninsula. The Gopeng has paid handsome dividends for thirty years, and promises a further life of at least fifty years. Other successful enterprises have followed, of which the Tekka, Tekka-Taiping, Rambutan, and Pengkalen are the best known. As for the future, Mr. F. Douglas Osborne succeeds to the chairmanship of the Malayan companies, and he and his partners, Mr. Chappel, Mr. Mair, and Mr. Glenister, will continue to exercise the technical control, while Mr. Wickett's sons will still attend to the financial and the stockbroking sections of the business. The high traditions are safe in their hands.

REVIEW OF MINING

Introductory.—The signing of a preliminary treaty with Sinn Fein has given general satisfaction in commercial circles, for it is felt that with Ireland settled it will be possible for the Government to devote more attention to the many financial problems in this country awaiting solution. Let us hope that the treaty will prove acceptable to all Irishmen, and that the new proposals will be given a fair chance by everybody. In mining circles the most interesting feature of the month is provided by the arrangements for gold prospecting in Nigeria. The metal markets have been more cheerful, and the prospects for the resumption of copper mining in America are distinctly brighter.

Transvaal.—News as to labour conditions on the Rand continues to be of varied character. The Government announcement, to which reference was made last month, did not have as much impression on white labour as was hoped at the time. The unions are now engaged in disputing multifarious points of detail. In particular, there has been a strike at Crown Mines, and the operations were entirely suspended for a time. Cable messages and other news sent to London do not elucidate the position, except that a conference has been called between the Chamber of Mines and the unions with a view to discussing possible economies.

The question of all-sliming, with or without elimination of amalgamation and stamps, continues to present a subject for discussion in this country, where no exact details of the new proposals are obtainable. The latest pronouncement on the subject, received by cable from South Africa, comes from Mr. J. G. Lawn, who mentioned in his speech at the meeting of the Johannesburg Consolidated Investment Company that the New State Areas plant would embody the principle of all-sliming. The new plant will have a capacity of 50,000 tons per month, and it is to be ready early in 1923. Speculation as to the nature of the process is naturally attractive to the average metallurgist, and in this case the question is, first, whether there will be any amalgamation, and, second, whether the cyaniding will be done in vats or by the counter-current system.

The meeting of the Consolidated Gold Fields was the occasion of another attack on the directors by Mr. Aubrey Hyman, a stockbroker with Johannesburg connexions. It is just eight years since he made a similar onslaught. On the present occasion he had omitted to fill the company's requirements as regards qualification for voting or speaking at the meeting, but by the grace of the board and of the shareholders he was permitted to make his speech. Nobody, however, came to his support in moving the resolution he had prepared, so the matter dropped.

Owing to continued losses, production at the Rooiberg tin mines was suspended at the end of September until the tin market recovers. Development is being continued, as also is the sluicing of alluvial deposits.

Rhodesia.—The output of gold during October was returned at 53,424 oz., as compared with 52,436 oz. in September and 47,343 oz. in October, 1920. The outputs of other products of Southern Rhodesia during October were: Silver 13,342 oz., coal 49,306 tons, copper 271 tons, asbestos 629 tons, arsenic 112 tons, and mica 21 tons.

The meeting of the Gaika company, one of the Gold Fields Rhodesian Development group, was occupied in much the same way as that of the Consolidated Gold Fields. Here Mr. Stanley Edwards agitated for a change of control, and the basis of his complaint was the old one about the disadvantages of a controlling company watching the share market as well as managing the mine. There is no denying the fact that a parent company, as a dominant shareholder in a subsidiary, has an advantage in the share market over the other shareholders, and it is therefore easy to fling unpleasant accusations broadcast though not so easy to produce definite evidence. In this case the decisions as to mine policy depend on current development owing to the erratic nature of the ore-bodies, and, moreover, Mr. Cyril Parsons, the consulting engineer, is not a man to write reports to order, so that the present hints are out of place. However, when the voting came, it was found that the shareholders wanted a change in the directorate, so Mr. Edwards was elected in the place of Mr. James Prinsep, the chairman. We understand that Mr. Edwards is now desirous that two other Gold Fields directors shall resign, and that Messrs. R. Rawdon Johnson and H. W. Edney shall join the board.

West Africa.—The reports of Prestea Block A and Abbontiakoon for 1920 were issued early this month. As mentioned some time ago the labour scarcity on the Gold Coast hit the gold mines badly last year. Prestea Block A treated 115,670 tons during the year, yielding gold worth £256,678, of which £61,923 represented premium; against

this were costs of £280,660. At Abbontiakoon 84,805 tons of ore gave gold worth £200,738, of which £17,982 accrued from premium, while the costs were £187,142. The ore-reserve position at Prestea Block A is giving rise to great anxiety. Developments at Abbontiakoon have added considerably to the reserve, but, on the other hand, the lode has not yet been found on the 16th level.

Nigeria. The Bisichi company has issued a statement relating to the exceptionally important developments on one of its properties, which was originally secured for the company by Mr. A. W. Hooke when he was in charge. It will be remembered that about a year ago this company absorbed the properties of its neighbours, which were under the same control, the Forum River, Ninghi, and Northern Nigeria Trust. The rights to the particular property in question were held jointly by the Bisichi and Forum River companies. Since the amalgamation this ground has been systematically tested under the direction of Mr. H. E. Nicholls, of the firm of Lake and Currie. The area is 3¾ square miles in extent, and is flat in the centre, with slightly undulating country beyond. The Forum River and its tributaries wind through the flats. On the northern bank of the present river there is an old river bed more or less parallel, and it is this ground that received first attention. By the end of June the deposit had been proved for a distance of 4,330 ft., averaging 970 ft. wide, to a depth of 21 ft. In all 577 bores and pits were sunk, and it is calculated that the area so tested contains 3,266,740 cu. yd. averaging 3 lb. of cassiterite per yard. Further pitting has since been done, and the results appear equally good, though exact data are not yet available. There remain lengths of ¼ and ½ mile respectively at the two ends still to be prospected, and also the flats on the other side of the river. This discovery is the most important made on the Bauchi Plateau for several years.

Prospecting for lode gold in the belts passing from south-west to north-east through Jebba, Birnin Gwari, and Kano continues to form an important feature of interest, and a number of exclusive prospecting licences have been applied for. On these, working options have been granted to several Nigerian and West Australian companies, among the latter being the Great Boulder Proprietary, whose manager, Mr. Richard Hamilton, has sent over one of his trusty prospectors, Mr. James Shea, to conduct the search on behalf of this company. Of individuals participating financially in the prospecting of this belt, Mr. John Waddington deserves special mention. He and Mr. Hamilton rely on Mr. Shea for a sound judgment as to the practical possibilities of the new gold areas, and there will be no rash promotions as far as they are concerned. It is generally believed that other individuals and companies taking interests in the same district will adopt the same cautious attitude.

The Nigerian Chamber of Mines has been pressing for reductions in charges of various sorts incidental to tin mining. A reduction in smelters' returning charge from £14 to £10 per ton has been secured for next year, and there seems a probability of railway rates being reduced before long.

Australia.—The companies at Broken Hill consider that metal prices have recovered sufficiently to warrant some extension of mining operations. The British Broken Hill is to restart mining, and the North and South mines are to increase their output. At the British mine, recent development at depth has given excellent results, particularly on Nos. 11 and 12 levels.

During the year ended September 30 the Mount Lyell company smelted 45,235 tons of North Lyell ore, 93,107 tons of Mount Lyell ore, and 14,343 tons of concentrate. The yield of blister copper was 5,786 tons, containing 5,738 tons of copper, 178,380 oz. silver, and 4,744 oz. gold. Recent diamond-drilling has indicated the presence of a large amount of additional ore. The profit was £51,830, but owing to present general conditions no dividend is paid. The directors are now applying to the Arbitration Court for a reduction in wages to agree more nearly with the reduced cost of living.

The Electrolytic Zinc Company of Australasia announces that the first unit of the new plant at Risdon, Tasmania, started running on November 22. The horse-power of this unit is 15,000, and the yearly output of zinc is estimated at between 20,000 and 22,000 tons. The second unit, of similar capacity, will be ready in about a year's time. The company will require additional capital to complete the plant.

Owing to the excessive cost of supplies and labour, it is no longer possible to win ore at a profit at the Bullfinch mine, and all operations have been suspended for a time. Options have been secured on territory in the Nigerian gold belt.

Hampton Celebration announces that a mill is to be erected, with a capacity of 100 tons per day. This should be ready to start in April. The proved ore above water level is estimated at 50,000 tons, and out of the profits accruing from its treatment funds are to be applied to sinking the main shaft further and testing the lode in depth.

Papua.—As the results obtained by the joint venture of the British and Australian Governments for exploring for oil in Papua have not been satisfactory, the British Government has withdrawn from the scheme, but the Australian Government intends to continue the investigations.

Burma.—The report of the Burma Corporation for 1920, just published, is not exactly cheerful reading, but in the present circumstances of the world's metal trade this is only to be expected. Particulars of output and reserves are given elsewhere in this issue. Conditions have rendered it necessary to postpone the erection of a new smelter, and to suspend the construction of the zinc works and the development of the Namma coalfield. Thus the company finds it is obliged to continue the policy of smelting ores, and later concentrates, high in lead and silver. The report does not mention the fact that Mr. E. P. Mathewson, the doyen of American metallurgists, is now in Burma, sizing up the position from both the technical and commercial points of view. It is to be hoped that the board will take his advice and give him a free hand. There is one point in the report of Mr. R. G. Hall, who recently completed his service as engineer in charge, that has proved disconcerting to shareholders ; we refer to his remarks about the difficulty in securing suitable labour. This question has not been mentioned in previous reports, but it is fully appreciated by those who know Burma, and has often received attention in the MAGAZINE, particularly in contributions by Dr. A. M. Finlayson and Mr. H. D. Griffiths. As regards the Bawdwin mines, there is no suitable local labour, and the Yunnanese who come to the mines in seasonal ebb and flow cannot be induced to stay in Burma during the rainy season from June to October. The Burma Corporation is now endeavouring to form settlements of members of tribes from the borders of the Shan States and Yunnan. We believe that these tribes, which are neither Shan nor Yunnanese, formed one of the difficulties when the boundary between Burma and China was settled, for each party wanted to hand over the territory to the other owing to the tribes not being amenable to discipline. It is gratifying to find now that these races are showing signs of being desirous of settling down to industrial life.

Elsewhere in this issue we publish an article by Mr. Harry D. Griffiths on the mineral resources of Upper Burma, in which he draws attention once more to the possibilities in connexion with the gold deposits of that country. Upper Burma is a comparatively new country as far as British mining operations are concerned. It was annexed in 1885, and for some time afterwards it was so unsettled as to be unfit for outsiders. In 1892 the Indian Government geologists had decided that King Thebaw's gold mines were not worth acquiring on public behalf. With such a judgment circulated broadcast it was clear that private enterprise would not be able to raise adequate funds for prospecting and exploitation. Consequently the early pioneers, such as Messrs. C. M. P. Wright, A. H. Bromly, and Trafford Wynne, worked under every sort of disadvantage, and had some pretty hard things to say of Government methods. In fact, the last named put it on record at a meeting of the North of England Institute of Mining and Mechanical Engineers in 1896 that the word "absurd" was the only one suitable for describing the mining laws and regulations imposed by the Indian Government. Things have improved lately, as Mr. Griffiths mentions, and there is now more encouragement for mining operations. Means of communication also have been improved, and fevers can be more easily combated. There has never been any doubt as to the great extent of the alluvial and eluvial gold deposits, but nowhere have deposits been found that can be called rich. Mr. Griffiths makes no claim for any such deposit, and looks to bucket-dredging on a large scale as the means for profitable work.

When the Indo-Burma Oilfields, Ltd., was formed last year the intention was to start work on the company's main property in Yenangyaung. Owing to the delays in receiving the plant, the engineers occupied themselves in prospecting the company's properties at Yenanma and Padaukpin, and the results were so satisfactory that well-sinking was commenced at those centres instead of at Yenangyaung. The reports now being received relating to oil-flow are most encouraging. The company has made a rearrangement of its policy. It will confine

its drilling operations to Yenanma and Padaukpin, and has made a deal whereby its Yenangyaung property will be drilled on a co-operative basis by the Yomah Oil Co. The refining is also to be done conjointly with the Yomah, and a company called the United Refineries Burma, Ltd., has been formed to inaugurate and carry on this work at Rangoon. Dr. Murray Stuart, late of the Geological Survey of India, has been appointed geologist to the company. It will be remembered that Dr. Arthur Holmes is geologist and also manager of the Yomah.

The British Burmah Petroleum Company is issuing £600,000 8½% second mortgage debentures for the purpose of financing an augmented development and drilling programme, both at Yenangyaung and at properties in a hitherto undeveloped oil area ; also for the purpose of completing the electric installation in the field and to extend and modify the plant at the refinery.

Malaya.—During the year ended July 31 the output of tin concentrate from the Pahang Corporation's mines was 2,269 tons, extracted from 169,931 tons of ore. In addition, 143 tons was obtained from alluvial ground, making the total 2,412 tons. The tonnage was less than during the previous three years, but the yield per ton higher. The cost continued to increase, and the fall in the price of tin had a serious effect on the income, so that the profit was only £9,260, as compared with £152,279 during the previous year. Development in depth has still been restricted owing to water troubles, but as the new pumps are now on the spot a resumption may be expected shortly. The reserve is estimated at over three years' supply to the mill.

Canada.—As mentioned in a recent issue, Mr. W. H. Goodchild was commissioned to make a geological examination of the Tough-Oakes, Burnside, and Sylvanite properties belonging to the Kirkland Lake Proprietary. He has now returned, and is submitting a report. Both he and Mr. S. C. Thomson, the consulting engineer, consider the present developments most encouraging. There is strong hope that it will be possible to start milling by the end of March.

United States.—The Tomboy company has suffered during the last few years from the worries that are general among gold mines in the United States, namely, increase of cost of labour and supplies without any compensating advantage accruing from a gold premium. The report for the year ended June 30 last shows that during the first part of the year the policy was to work as much of the better grade ore as possible, and to restrict the tonnage ; subsequently the new manager, Mr. N. F. Kelsey, found that the best ore was rapidly diminishing, so he adopted the policy of working a maximum amount of average ore. The total ore milled was 197,557 tons, an increase of 51,491 tons as compared with the previous year. The yield of gold as bullion and in concentrates was worth £223,694, and the working profit was £18,006. After allowances for depreciation and taxes the year ended with an adverse balance of £2,681. During the last year or two development has necessarily been restricted, owing to lack of suitable labour, and in addition many of the workings fell into disrepair. Development of the Virginius vein, which contains ore of a better class, is now being pushed, and it is hoped this source of ore will be available shortly.

Mexico.—The directors of the El Oro company report that conditions in Mexico have improved recently, and that, in consequence, the costs have been reduced \$1·00 per ton. Thus it has been possible to work ore of lower grade. During the year to June 30 last, gold worth \$2,545,446 was extracted from 383,043 tons of ore, resulting in a profit of \$357,010, or £95,202. Railway profits were £54,273, and interest and dividends brought £31,124. The company is saddled with big taxation, having to pay \$333,297 in Mexico and £56,800 here. The shareholders received £57,375, being at the rate of 5%. Owing to poor results and the great heat, development has been abandoned on the 2,200 ft. level on the San Rafael vein. The reserve is estimated at 282,124 tons, averaging \$7·96 in gold and 2·11 oz. silver.

China. — The Chinese Engineering & Mining Company reports that the net profits of the Kailan Mining Administration (the company that controls the marketing of the coal produced by this company and the Lanchow company) for the year ended June 30 were \$7,313,448, of which the company's share was \$3,850,012, equivalent to £527,371. Out of the profit £261,220 was allocated to British taxation accounts, and £308,000 was distributed as dividend, being at the rate of 22% tax paid. The sales of coal by the Kailan Administration during the year were 3,775,379 tons. Investigations are still proceeding with regard to the establishment of an iron works at Chinwang-tao.

MINING POSSIBILITIES IN BURMA

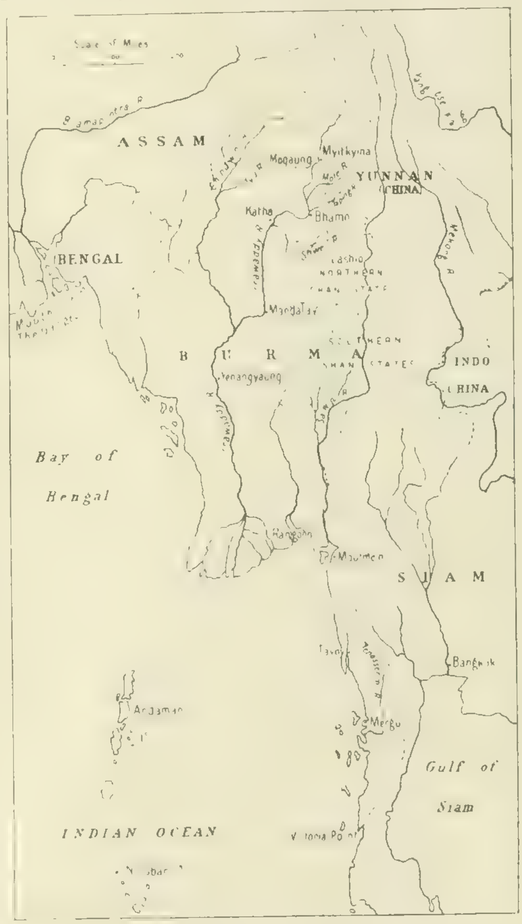
By HARRY D. GRIFFITHS, A.R.S.M., M.Inst.M.M., M.Inst.C.E.

The Author shows that the mineral resources of Burma are not fully appreciated by the general public, and presents evidence that there are many opportunities for profitable ventures, particularly in connexion with gold-dredging.

INTRODUCTION.—Burma attained some fame as a mineral-producing country during the Great War, when the production of wolfram under pressure from the Government of the Province was brought up to a high figure. Many of the mercantile firms in Rangoon, which previously had not been particularly interested in mining operations, were urged to devote some of their capital to the mining of wolfram. The industry was controlled by the Government, which bought the tungsten ore at a price of 57s. 6d. per unit, and made also an allowance to cover the fluctuating price of the rupee. Many properties in the district of Tavoy, Lower Burma, were equipped and manned by the best available labour, and by the beginning of 1918 the production of that district was at the rate of over 6,000 tons per annum, practically equal to the pre-war production of the world.

In most instances the ore was obtained from surface quarrying of the veins, and very little underground work was done. Advance development was totally neglected, and the mines had only a hand-to-mouth existence. The cost of labour and material having largely gone up during the war, the mining enterprises at the best just paid their way, and it is very doubtful if the commercial firms engaged made a 10% profit on their outlay.

The price guaranteed by the Government was to continue until twelve months after the end of the war, and on the strength of this several of the regular mining companies enlarged their equipment and staff so as to place themselves on a footing appropriate to their resources. Less than six months after the Armistice, the Government withdrew their guarantee and offered a compensation commensurate with what each mine should have produced during the full period. The compensation was liberal in the case of individual mines or miners that had no outlay in machinery and plant, but proved totally inadequate for those serious enterprises that had spent large sums of money in equipping themselves in a proper workmanlike fashion. The demand for wolfram rapidly decreased and the price quoted for tungsten ore very quickly became nominal. By the end of 1919 it is reckoned that the Government had on hand some 6,000 to 10,000 tons of wolfram, which presumably it proceeded to sell. The quotation promptly dropped to about 12s. 6d. The result, as far as Burma was concerned, was a practical stoppage of the industry.



MAP OF BURMA.

That a partial stoppage was to eventuate sooner or later, even with a fair price for the metal, was foretold by the writer, who pointed out that surface scratching of

lodes could not last long when no development in depth had been undertaken. Had the local Government insisted upon a percentage of the profit obtained by the small owners being devoted to underground development, a potential industry would have been established; and would have been in a position to restart as soon as prices had again become reasonable. As it is, however, with the exception of a few of the serious enterprises already mentioned, the wolfram industry of Burma will not be of any importance in the future unless a large amount of capital be put into development and plant.

The few companies which are still holding on manage to do so on account of the tin ore which exists in connexion with their wolfram deposits. The largest producing mine yields ore containing half tin and half wolfram, and the next one in importance is now working the foot of a detrital talus, which produces practically clean tin ore.

The production of tin in Burma has never been an important one, as for many years the only tin ore exported was that which occurred with the wolfram, and from which it was separated. During the early part of 1920 the abnormal price prevailing for tin induced a search for tin ore, and led to many discoveries being made, which will be referred to later.

As regards other base metals, Burma has proved itself of some importance. The company operating the Bawdwin mines has spent a lot of capital in opening out and equipping the well-known deposit of zinc-lead-silver ore. The development continues in a most satisfactory manner, and there is no doubt that on completion of their new smelter a handsome profit will be obtained. Gold mining has also been tried in the past, but owing to a concatenation of adverse circumstances has not been profitable and came to a stop.

The present position of Burma as far as metal mining is concerned, is therefore that it is undoubtedly a metal-bearing country, but that it has not yet given any profit on the capital invested in mining. This fact has led a good many engineers, after a short sojourn in the country, or the examination of some particular spot, to state that Burma is not a mining country.

The writer has now been in continuous and intimate touch with Burma for the last eight years, and has probably done more individual prospecting, testing, and development than any other engineer, and he has come to the conclusion that there are many mining propositions capable of being worked profitably. These will be described later.

Some of the main drawbacks to mining have been the difficulties of communications, and the reluctance of the Government of India to allow any adequate expenditure on roads and tracks to mining districts. It is a pleasure to state, however, that the local Government seems disposed now to help the development of the country by every possible means. A new post of Development Commissioner has been created, and already it has shown its anxiety to be of all possible help to the industries of the country. Questions relating to mining are now considered by the Development Commissioner, instead of going through the routine of several other departments, whose decisions, owing to want of intimate knowledge, were slow and mostly unfavourable to the miner. Mining matters are promptly attended to by the Development Commissioner, whose department is provided with special powers and funds to be devoted to any urgent work. It generally took from two to three years for an application for a mining lease to be signed and delivered. Now it can be all fixed up inside of six months.

Causes that have retarded Mining Development.—Before considering a mining country it is essential to carefully consider the reasons why the pioneer mining companies have failed to make good. Unfortunately this is not often done, and the layman, judging by past results only, is prompt and emphatic in his condemnation. Burma has had to struggle through all the same difficulties as other mining countries have had to contend with, and is still under a cloud. There is not any doubt whatever that with a little more confidence in the industry and its present leaders, Burma will emerge from the cloud, and will become an important factor in Imperial production.

The foremost industry of the country, that is, the petroleum industry, has been the only one so far that has gone prosperously from the start. Its success has undoubtedly diverted a lot of capital which otherwise might have found its way into prospecting mining ventures. That industry is still making vast strides. Systematic search is conducted continuously, and new discoveries of oilfields are being made. Virgin oil ground, in the writer's opinion, exists west of Mandalay and the Irrawaddy, also in the Upper Chindwin, and recently a discovery

of oil-shales, reputed to be higher in oil contents than the Scottish shales, has been made in the Moulmein district. The Akayab district, also, has not yet said its last word. If, therefore, the oil industry could legitimately be classed as a mining industry, Burma would indeed be reckoned as a foremost mining country.

The jadeite mining industry is unique to Burma, but owing to the condition under which exploitation is allowed, there is no room for any investment or commercial expansion in that line, and the Government derives little from this source. The ruby industry has been carried on for many years past, but of late, owing to conditions created by the war, it has not been remunerative. The gem-bearing ground is very far from being exhausted, and, in fact, new ground is constantly being opened out, and there can be little doubt that the industry will soon again become a profitable one. In the base-metal line, one of the most important deposits in the world of zinc-lead-silver ore has been, as already mentioned, opened out in a very extensive way at the Bawdwin mine. Lead and silver only are being extracted at the present time at a very substantial profit, and as soon as the new smelter is completed the production will be on a very large scale, and the shareholders will receive handsome dividends on their investment. Had it not been for the unavoidable delays due to the war, to the subsequent dislocations of home industries, and lack of Government assistance in the way of providing means of communication, that result would have been achieved by this time.

The wolfram mining industry has had to contend with many difficulties in the shape of patchiness of the lodes, pinching or impoverishment in depth, inefficient labour and management, want of necessary machinery, etc., and can be said to have been remunerative only during the period of the war. The best and most durable mines have been exploited by means of English capital, but the bulk of the war production has been produced by individuals or small local concerns working small reefs and patches at the surface. On resumption of mining when the rise in the price of wolfram has taken place, those properties only which have been scientifically equipped and managed will be successful.

Tin-mining has become a regular industry only since the end of the war, and the practical cessation of wolfram mining. Most of the tin now produced is obtained from alluvial ground and eluvials. Tin-dredging has been carried on very successfully for many years in the Tavoy district by two enterprising miners. Some two years ago this enterprise was acquired by one of the leading mining companies in Rangoon, who at once proceeded to erect a large and up-to-date bucket-dredge. This dredge commenced operations this year when the price of tin was favourable, and gave magnificent returns, which should have enabled the company to distribute immediate dividends. Unfortunately the price of tin suddenly dropped down to an undreamed of figure, and has since continued at that low level, so that although the returns even now more than cover the costs, dividends are not likely to be forthcoming until the price of tin reaches at least £175. Had it not been for this misfortune the tin-dredging industry would by now have firmly established itself as a remunerative one. This desideratum is, however, only postponed, and is sure of achievement.

One other large company which was working wolfram had to cease that class of work when there was no market for wolfram. Fortunately, however, a tin deposit has been discovered at the foot of the huge talus which provided most of the wolfram, and all the hydraulicking plant was turned on to it. The tin production soon become an important one, and at the price then prevailing for tin a handsome profit was in view. The sudden drop in the price since the beginning of this year has, however, destroyed the hope of dividends, and the mine can now no more than pay its way.

Two other large companies working on wolfram-tin ores have had lately to cease operations for the same reasons, although they had been dividend-paying concerns previous to that.

Some years ago attention was paid to gold mining, and four dredges were put to work in the upper reaches of the Irrawaddy. This work was carried on with variable fortune. The operations were confined to the actual river-bed, and apparently little was thought of the gold wash in the bank. The work of the dredges was very irregular owing to machinery troubles, and to time being wasted in working round the river bars to look for intervening pockets; and although at times one dredge could return

1,000 oz. per month, the operations as a whole were unprofitable and came to an end. The reasons ascribed for this failure appear to be many, among which were suspected gold thieving, expensive management, overstaffing, and poor knowledge of gold deposits. The failure of this concern put a complete stop to all gold-prospecting operations in Burma, and created a strong adverse feeling towards gold mining.

At about the same time another property, which had been inspected and reported upon favourably by two well-known and trustworthy engineers, was floated, and a dredge was ordered. The dredge was duly received in Rangoon and then forwarded on to the spot. The only way to reach the property, however, was by going up a small and shallow river some 120 miles. This journey could only be accomplished during the rainy season, when the river became practically a swift rushing torrent. The machinery placed in shallow-draft country boats began its journey, and a succession of accidents deposited it all at the bottom of the river. No part of this machinery, it is believed, ever reached the property, and another disappointment was thus added to the experience of the gold-mining investor.

One gold-quartz proposition was capitalized, equipped, and started. The returns were sufficient to enable paying back a debenture issue, and dividends to the shareholders, when suddenly the management reported that the reef had "dropped down" too deep to be exploited successfully, and the concern was wound up before the investor had had his investment returned in full. Thus was one more nail added to the coffin of gold mining, but it is only fair to say that the pioneers of this venture worked under very disadvantageous conditions and discouragements.

Recently a well-known engineer, representing the biggest gold-mining firm in India, visited this mine, and it is whispered that after having put in a short cross-cut he struck the faulted reef and obtained high values. In any case the fact is that active development has since been carried on at that mine, and that considerable extension of development is being considered.

Several other occurrences of gold have been reported, but owing to there being no adequate means of communication, and a lack of confidence, the schemes for exploitation came to nothing.

Taken as a whole, therefore, but with the exceptions mentioned, mining in Burma has not been tackled properly and seriously.

MINERALS IN BURMA.—That Burma is destined to become a mining country is shown by the following list of metals and minerals that are now being exploited, or whose existence has been definitely ascertained :—

(1) Now being exploited (mineral oil excepted) : Wolfram, tin, lead, copper, zinc, silver, gold (by natives), jadeite, rubies, and zircons.

(2) Ascertained or in course of development : Gold, platinum, bismuth, antimony, graphite, oil-shales, coal, etc.

The writer has explored many parts of Burma, and his observations have led him to the conclusion that, outside of present exploitations, great possibilities exist (in order of importance) in gold, platinum, and tin.

The list may not be a very large one when compared to some other countries, but it makes up in containing those particular metals for which there is at present, or soon will be, a great demand.

GOLD.—All the early explorers are unanimous in mentioning the occurrence of gold in many parts of Burma, and at the present time there are many thousands of natives working gold in many directions. The production from this source does not appear in the Government's official returns, for the good reason that it is not declared, and finds its way out of the country or to the local bazaars without any benefit to the Government. It will, however, astonish many to see what the official gold production has been during the last few years, in spite of the fact that only at the most two properly constituted companies were at work. The production has been as follows :—

Year.	Ounces.	Estimated Value in Rupees.	Value per ounce in Rupees and Annas.	
1905	621	36,278	58	6
1906	2,301	1,32,830	57	11
1907	3,837	2,23,844	58	5
1908	6,950	4,59,060	66	—
1909	8,488	4,91,972	58	—
1910	5,996	3,45,740	57	8
1911	6,421	3,65,662	56	14
1912	5,068	2,90,058	57	3
1913	5,393	3,11,501	57	12
1914	3,704	2,14,425	57	14
1915	3,182	1,85,025	58	2
1916	1,892	1,15,638	61	2
1917	1,078	63,718	59	14
1918	171	11,089	66	14
1919	38	3,421	90	—
Totals and Averages	55,140	32,50,261	58	14 = £4.

The gold occurrences of Burma can be classed into three groups: The Upper Chindwin, the Bhamo district, and the River districts.

Upper Chindwin.—In this district the older rocks are covered by an enormous area of a loose conglomerate which carries gold. The denudation flow has apparently been from north-east to south-west to the Uyu Chaung (a tributary of the Chindwin River), which can be considered as the southern limit. The conglomerate comprises enclosures in the shape of well-rounded boulders of all the older rocks to be found in the vicinity, including boulders of jadeite, as well as granites, quartzites, and other rocks, which so far have not been found in that part of the country. In some instances this detrital deposit attains an enormous thickness, and in a portion of the right bank of the Uyu can be seen rising perpendicularly for 300 ft. from the river's edge. The boulders are generally cemented by fine grit and sand, with little clay, but in places iron infiltrations have taken place, and have transformed the conglomerate into a hard one.

Subsequent denudation has bared the underlying country rock in places, and has caused a concentration of the gold all along the Uyu Chaung and its tributaries on the right bank. Every creek on this bank is prolific in gold, and many hundreds of Cochins exploit it after each rainy season. In some of these two natives, fossicking among the boulders produced, at the time of the writer's visit, from ½ to 1 oz. per day. In these small valleys and creeks the writer found gold in all parts of the conglomerate, and many cross-sections tested gave an average of 3 to 6 grains per yard.

The particular feature of the gold is that it is almost invariably associated with platinum. The average sample taken by the writer yielded 75% gold and 25% platinum, which could easily be separated. The fineness of the gold is between 825 and 900. The washing of the conglomerate bulk samples was done in a very rough sluice-box, cut out solid from a small tree, and, of course, the fine gold was not recovered.

Along the course of the Uyu River there are many bars running across, above and below which coarse gold and platinum are found. An attempt has been made to exploit these, either by diverting the river, or by means of divers, but owing to the presence of large boulders the operations, as was to be expected, were not successful. There are also many "flats" along this river in which the conglomerate is exposed, and which, given a sufficient area, would render dredging operations possible. In many parts, the conglomerate could be exploited by hydraulicking, but the difficulty lies in the want of storage places for water. Near the river itself water could always be obtained by pumping, but this method would probably not prove remunerative. The writer has only explored a small portion of the area, but has seen sufficient to convince him that further systematic exploration will reveal many portions worth exploiting. The boulders of jadeite in the conglomerate occur mostly to the south of Tamaw, where the celebrated jadeite has been exploited for many years. They are not very numerous, but make up by their being of large size, and containing the dark green variety of jadeite so much prized by the Chinese, and which is now unobtainable in the Tamaw mines, and realizes a high figure. In this particular portion of the gold conglomerate, it has been reckoned that the realization of the jadeite boulders would cover the costs of hydraulicking, leaving the gold as profit.

In contemplating exploitation of the Upper Chindwin conglomerate some serious drawbacks will have to be reckoned with and overcome. During the monsoon season communication with either Mogaung or Myitkyina is almost impossible, owing to lack of roads, bridges, etc., and at other times the whole of the traffic is done by mule transport. A remedy to this state of affairs is not impossible, but it would necessitate assistance on the part of the Government. Fever is bad in the district, and the whole native population for that reason, and also because no work is possible during the rains, migrates *en bloc* to higher ground, to return when the sun again shines. The local inhabitants do little cultivation, and confine their efforts almost exclusively to working the jadeite deposits, which absolutely belong to their chiefs, who only pay a small royalty to the Government. They would not do for steady employment, but Yunnanese coolies, who are physically a fine race, with greater powers of endurance than the local natives, could be obtained in any number from across the eastern border. These Yunnanese have the monopoly of mule transport in that part of Burma, and stream across the border with their

hundreds of ponies when the rains cease. The local natives are peaceful enough, as long as there is no interference in what they consider their rights, and it is certain in the case of some properties on the Uyu River, where they now exploit the gold in the creeks, that some amicable arrangement would have to be brought about before starting work on a large scale.

These drawbacks are, after all, no greater than miners have encountered in other countries, and with a little perseverance and

Fig. 1.—Gold Wash in Terrace above River Level.

tact can be overcome, but so far they have been sufficient to retard enterprise.

In addition to the syndicate which was formed to exploit the Uyu river bed, only one other local syndicate has made an effort at exploitation. The failure of the latter was not due to the poorness of the gold wash, but to the difficulty of impounding water for hydraulicking in quantity sufficient to last over the dry season, and want of cash to hold on until the next rains arrived. In these two cases, again, local want of confidence in gold-mining seriously interfered with the securing of valuable data.

It is hoped that the detailed Geological Survey, which is extending in that direction, will give valuable indications as to likely gold deposits, as it did in the case of wolfram and tin in Lower Burma.

Bhamo District.—The district is very easily accessible and possesses rough tracts running parallel to the Irrawaddy and skirting the foot of the hills that rise from the Irrawaddy basin to China, and several of the tributaries of the Irrawaddy can be utilized for transport of machinery. Several tracks also radiate from Bhamo to China (Yunnan) across the hills, and during the dry season a large amount of traffic to and from China, by pony transport, takes place. The hills form the eastern edge of the Irrawaddy basin, which at one time, between the first and the second defile, was probably a huge lake, the western shore being represented by the range of hills running south from Myitkyina. Several rivers whose source is in the high country of Yunnan have cut their way through the ranges, flowing in a westerly direction, and cutting through the flats until they reached the Irrawaddy. A large flow of denudation has taken place from east to west, and has resulted in the deposition of a detrital gold wash all over the western flank of the hills, over a distance of many miles, say, from Mandalay to Myitkyina. This wash has filled in the inequalities of the slopes until the rivers and streams flowing west have cut through. The principal of these rivers are from south to north, the Shweli, which merges into the Irrawaddy south of Katha, the Taping River, 24 miles north of Bhamo, the Mole River, 30 miles further north, and the Namsang River, a further 12 miles. The original denudation brought the detrital matter right into the Irrawaddy lake, where with the assistance of the subsequent streams it became a typical alluvial deposit, filling up the lake and producing the present flats. This alluvial has been spread right across the basin to the hills west of the Irrawaddy. For many years past the terraces of the original detrital wash have been exploited on the flank of the hills by natives. The flanks are dotted by innumerable pits and quarries, but in the flats, owing to their being waterlogged, no work has been done. The gold wash in the flats is undoubtedly a re-sorted deposit, from which have been eliminated certain enclosures of friable and easily decomposed rocks, which are found in the original deposit in a very decomposed state, thus leaving water-worn enclosures such as quartzites, hard schists, and quartz.

A difference in the appearance of the two kinds of wash will be evident from the accompanying photographs. Nos. 1 and 2 show quarries in the terraces high above water-level, and No. 3 the re-sorted wash on the river bank.

The writer has put in more than two years of exploration of these deposits, and is still wondering why such enormous wealth has so long remained undeveloped. The detrital terraces are richer than the re-sorted wash in the flats, and where tested by extensive sluicing have yielded a value of 8 to 11 grains per cubic yard. A large number of bores in the flats have given an average of 6 to 8 grains per cubic yard, and have proved conclusively that from the foot of the hills the bed-rock slopes at a very slight angle so that at a distance of 2½ miles it lies at a depth of only 60 ft. This helps to support the contention that the flats were at one time represented by a shallow lake, and that there is an untold quantity of ground to be worked at very reasonable depth.

The feature of the re-sorted wash is that at all points it carries gold from its very top, and the increase of contents with depth is very rapid.

The three most important properties in this district have been taken up and thoroughly tested by an enterprising local syndicate, called the Tavoy Tin Syndicate, which had been formed originally to look for alluvial tin deposits in the Tavoy district. The syndicate's work in this line will be detailed further on. The three gold properties have been selected at those points where the Taping, Mole, and Namsang Rivers emerge from the hills on to the flats, and where naturally the greatest amount of concentration of the re-sorted deposit has taken place, and the prospecting has fully confirmed the deductions of the syndicate's engineer. All these properties contain terraces of the original wash, as well as a large extent of the re-sorted wash. For instance, the Mole property contains over 150 million cubic yards of 6 grain wash, the Taping property 30 million cubic yards of old terraces of a value of, say, 8 grains (some spots yielded 1 dwt. 12 gr.) and 2,000 acres of dredging wash, and the Namsang property has some 3,000 acres of wash. These three properties are the only ones which have been taken up so far, and they show as mere dots on the map of the area that is covered by gold wash.

FIG. 2. GOLD WASH IN TERRACE 30 FT. ABOVE RIVER LEVEL.

The local prejudice against gold is still

so strong that in all probability the capital needed for the exploitation of these properties will have to be secured abroad. Tempting offers from America have been received for the purchase of these properties, but, unfortunately, the Burma laws do not allow any foreigner to hold more than a 40% interest in a mining property, and, of course, American money could only be put up on the condition of American control.

It is quite certain that had such an extensive field been found anywhere in or near the United States dozens of powerful dredges would have been at work long ago. The bucket-dredging conditions throughout the district are ideal, good even soft (decomposed schists) bottom, no clay, no large boulders, no sunken logs, water for paddocks always abundant. The terrace and re-sorted wash is quite loosely cemented, and in no place so far has any laterite been found. The gold is generally fine, but easily concentrated, and has a fineness of 900 to 925. An occasional trace only of platinum has been spotted, but galena very rich in silver, native silver, etc., are found in the concentrate.

The writer has explored the hills right up to the China border, but has failed to locate any veins, the denudation of which might account for the presence of the gold in the wash. In fact, the boulder enclosures of the wash are mostly of rocks, which only occur a long way east in the high mountains of Yunnan. The failure of proving the existence of gold reefs is of no consequence when one considers the huge amount of detrital gold which is begging to be extracted. The writer is confident that in time the Bhamo district will become an enormous goldfield.

The Shweli river joins the Irrawaddy through a series of hills, below the great Irrawaddy basin. It does not emerge into extensive flats like the properties described, but along its course it has many basins or flats, filled in with wash of high value. The successful exploitation of these is dependent upon their extent and contents, and also on their accessibility. At the present time access to these flats is difficult, and often several ranges of hills have to be traversed to reach them, but there is no doubt that in the future the present difficulties will be surmounted.

THE RIVER DISTRICTS.—These may be said to comprise the river and immediately adjoining flats of the Irrawaddy from, say, 100 miles north-east of Myitkyina to the second defile south of Bhamo, and the whole of the course of the Salwin River with all its tributaries inside the borders of Burma.

As already described, a serious attempt, ending in failure, has in the past been made to exploit the Irrawaddy bed in the vicinity of Myitkyina. The probable reasons of the failure have been described, and it has struck the writer that the work has been too much localized in a southerly direction from Myitkyina, where both banks of the river are rocky and eventually rise to form the first defile, and that sufficient attention has not been paid to the flatter portions to the north, where the banks of the river show a re-sorted wash similar to that of the Bhamo district. A broad view of exploitation does not seem to have been considered, and the greatest effort was directed to the cleaning out of the rich pockets in the actual bed of the river.

Wash is also obtained south of the first defile mentioned, and is undoubtedly the western continuation of that obtained in the eastern portion of the basin. This wash, being in some instances 15 miles away from the point where it began to be re-sorted, may not prove as high in value as at, say, the Mole River, but there is no evidence to show that it is of unprofitable value. The fact that at Mole River the wash at a distance of 2½ miles from the foot of the hills does not show any appreciable decrease in value, as compared to the nearer ground, would give hopes that even much further away it would probably still be rich enough to justify exploitation. The flats above the defile have a better chance as they are very much nearer to the foot of the hills, over which the wash has poured west.

In places, owing to the inequalities of the old lake bottom, the wash will be found to extend beyond practical dredging depths, but it is thought that the majority of it will be obtained within 50 to 70 ft.

Below the second defile, and for some considerable distance to the south, gold wash is occasionally seen in the bank of the Irrawaddy, especially in the vicinity of the confluence of the Shweli river.

On looking at a map of the country, it is at once seen that the name of many of the villages, streams, hills, etc., begin with the prefix "Shwe", which in Burmese means gold or golden, and this goes to show that for many generations the presence of gold has been ascertained.

FIG. 3.—GOLD WASH IN RIVER BANKS

FIG. 4.—TWO-FOOT SLUICE-BOX USED IN BULK SAMPLING.

FIG 5.—DREDGING FLATS OF BHAMO DISTRICT.

All the early explorers who attempted to penetrate China by following the course of the Salwin River have reported large native gold workings all along its banks. Later exploration has shown that gold is still being worked on many of the tributaries, either just above water-level in the low ground or up the hills at a considerable height above.

Unfortunately the river Salwin is very difficult to navigate, owing to its many rapids, etc., and its access from the Burmese side is a very difficult one, owing to the rough nature of the country which has to be traversed. Some of the smaller rivers west of the Salwin and running parallel to it have been proved to contain gold. In fact, one or two properties have actually been tested by boring and quarrying, and have shown the re-sorted wash to be of about the same value as that in the Bhamo district. As far as can be ascertained, there are only a very few places where intense reconcentration in certain creeks has made the gold contents sufficient to repay individual diggers, and most of the deposits will only prove remunerative on being worked on a large scale by up-to-date methods.

The occurrences thus described are sufficient, it is thought, to dispel all doubts as to the presence of gold in remunerative quantities in Burma.

TIN.—A systematic search for tin can only be said to date from the end of 1919. Previous to that year very little work was done on tin deposits and the Burma output was practically all obtained from the separation of the tin ore occurring with the wolfram. Dr. J. Coggin Brown, whose name is very familiar to the readers of these columns, happened at that time, and since early during the war, to be mining adviser and chief inspector of mines to the Government, and in that capacity examined geologically the whole of Lower Burma. He particularly pointed out such places in the Tavoy district where alluvial tin might be looked for, but did not get very much response from prospectors. At that time the Tavoy Tin Syndicate had begun its existence, and was prospecting or securing such properties as would be likely to prove tin-dredging propositions. Prospecting was done on eight different properties. In every instance tin wash was obtained. With the exception of one or two properties, however, the tin ore proved to be unevenly scattered, and the wash in quantities too small to justify exploitation. The one exception proved to be a flat in the Pauktaing River, below the point where a suction-cutter dredge had worked successfully for several years. Hundreds of bore-holes proved the value of the ground to be $\frac{3}{4}$ lb. per cubic yard of 70% cassiterite. As far as the writer has been able to ascertain, not many dredging properties will be found in the Tavoy district, but there are many detrital deposits containing tin which will be exploitable by hydraulicking methods.

The tin resources of Burma are found principally south of the Tavoy district, in the Mergui district. Here the topographical conditions are somewhat different. The detailed geology is also different, and more akin to that encountered in the Federated Malay States. Limestone, pegmatites, and phyllites make their appearance, but granite intrusions are few. In many parts of the district these older rocks are covered over by Tertiary deposits. In the hilly ground north of the Tenasserim river, wolfram lodes have been worked, and all the streams flowing to the river to the south, or to the sea to the west, contain patches of tin wash. Many of these are exploited by individual miners, and are made to pay for themselves, but it is doubtful whether there are any patches large enough to justify bucket or suction dredging. South of the Tenasserim, the Mergui series appear to contain more quartzites and phyllites. These are generally largely impregnated with tin, in the shape of well-defined crystals along all the bedding- and cross-planes, forming in places a regular stockwork. This cassiterite is of great purity and very black. In parts of the district, the denudation of these quartzites, sandstones, and phyllites has resulted in some important alluvial deposits, and extensive talus on all the western slopes of the ranges. Another prolific source of tin in the district is the presence of large masses and intrusions of pegmatites. At the surface these are highly decomposed and can easily be washed down, but in depth they become so hard as to necessitate blasting. Near the surface these pegmatites yield from 1 to 3 lb. per cubic yard, and in depth, where tested, the maximum value has been 5 lb. The denudation of these has filled in many depressions in the valleys with a wash carrying tin in profitable quantities. Many of these filled-up basins are worth exploiting by dredging methods. Going further to the south, there are numerous flats, valleys, etc., both on the mainland and in the islands,

containing tin wash, and this continues to Victoria Point, the southern boundary of Burma, just beyond which the Renong Company, the Siamese Tin Syndicate, etc., are being operated so successfully. It can, therefore, be said that the whole of the country south of the Tenasserim to the border is tin bearing.

The means of communication overland are *nil*, and the country is gradually being penetrated from the sea border.

One of the most important discoveries of tin in the district is the Thabawleik mines, which lies some 70 miles from the sea-coast, and is reached by navigating up the Tenasserim and Little Tenasserim rivers. Here an enormous valley is filled in with typical alluvial tin wash, of a depth of 15 to 25 ft. The deposit is very even and has been actually shown to exist over many hundreds of acres. A large number of bore-holes have given an average of 1·4 lb. of 75% cassiterite per cubic yard. The whole of this deposit lies on Tertiary and Devonian rocks lying horizontally, and which contain important seams of coal. One of these being opened up by the Thabawleik mines for their own use is of excellent quality, and much superior to the Rawang coal, which is so extensively used by the dredging companies in the Federated Malay States. It is supposed to be of Devonian age, and on analysis by a specialist gave the following results :—

	%
Moisture	5·30
Volatile hydrocarbons	32·15
Fixed Carbon	47·50
Ash	15·05
	100·00

Calorific Value 12,214 B.T.U.

The coal gives 62·55% of good hard cake carrying 2·33% of sulphur.

Above this property a huge talus at the foot of the hills carries cassiterite in large quantities up to 15 lb. per cubic yard, and the slopes of the hills show stockworks in sandstones capable of exploitation by hydraulicking.

The writer is convinced that this part of the Mergui district, down to the south boundary, is destined to become in the near future a very important tin-field. Its development is necessarily slow, owing to the difficulties of access and the limited amount of local cash available for exploration, but it is satisfactory to note that a certain amount of exploration is already taking place, which is financed from abroad, and success will inevitably be achieved in the near future. The Mergui district is destined to help the Empire maintain its preponderance in the world's tin production, in spite of many difficulties which may be encountered. The only thing needed is fresh capital, which a small country like this cannot itself furnish, and which it must try and secure abroad.

The conditions of tenure of mining ground in Burma are not at all onerous, the titles are unchallengeable, and the Government royalties are very much less than in any other country. For instance, gold is subject to a royalty of 2½% *ad valorem*, tin and wolfram to 30 rupees per ton. Ground rent and quit-rents are also charged for, but for any producing property, in which the amount of royalty exceeds the total of the rent, only the royalty is payable, and vice versa. The royalty on coal is 6 annas per ton, and only 2 annas for coal used on the property itself.

Coal.—So far this has never attained a place in the products of Burma. Inland the industries are dependent upon a very large and cheap supply of wood, and on the sea-border a good deal of coal imported mostly from India is used.

Huge deposits of mostly Tertiary coals have now been ascertained, and some of them are now being opened out, in such districts as are handy to meet local demand. The coal everywhere appears of very serviceable appearance, and similar to that described above. Owing, however, to its light specific gravity and low calorific value, it cannot be expected to compete against Indian coal for bunkering. It will, however, serve for coke making, use in smelters, on railways, river boats, and in all the numerous rice, oil, timber, and cotton mills of the country.

Conclusion.—The subject of Burma's mining future has of necessity been dealt with very briefly in the above notes, but it is hoped that it may draw the attention of our leaders of industry to a bright prospect. British mining enterprise has never been one afraid of difficulties, and the few drawbacks of Burma will be considered as very small compared to others which have been successfully surmounted. A handsome reward awaits the enterprising miner and investor.

VENTILATION AND WORKING EFFICIENCY

By BERNARD W. HOLMAN, O.B.E., A.R.S.M., Assoc.Inst.M.M., F.C.S.
Lecturer in Mining, Royal School of Mines

The author discusses the modern principles of ventilation and working conditions as applied to deep and hot mines.

(*Concluded from November issue, page 286.*)

THE USE OF THE KATA-THERMOMETER. To use the instrument for measuring purposes the bulb is heated in warm water at about 80° C. (this can be carried about in a Thermos flask) until the spirit (coloured red) rises into the top reservoir. The column must be free from bubbles, and care must be taken not to let the top reservoir fill, otherwise the instrument may burst. The instrument is then allowed to cool, and the time in seconds taken in cooling from the 100° mark to the 95° mark is noted with a stop watch. The first reading should be neglected so as to allow the glass time to get into equilibrium. The mean of three or five readings may then be taken as desired. This mean time (T) divided into the factor (K) of the particular instrument gives the cooling power (H) directly in millicalories per square cm. of cooling surface per second. One millicalorie per square cm. per second is equal to 0·4 milli B.T.U. (thousandths of a British Thermal Unit) per square foot per second. Each instrument is carefully calibrated by the makers and the factor (K) engraved on the back of the stem. This factor is determined by observing the dry kata cooling power in still air at a standard temperature, t. When the temperatures are expressed in degrees Centigrade, and 36·5 is the mean temperature of the kata during the observation time T, the factor is given by the empirical formula $K = 0{\cdot}27\,(36{\cdot}5 - t)\,T$. But we also have by definition $K = H_d\,T$, where H_d is the dry cooling power. If the difference between this mean temperature and the temperature of the working place be expressed by θ, we get the dry kata cooling power H in millicalories per square cm. per second represented by the formula $H_d = 0{\cdot}27\theta$, where the air is still, but when it is moving Dr. Leonard Hill found by experiment that $H_d = (0{\cdot}27\,t + 0{\cdot}49\,V^{0\cdot5})\,\theta$, where V is the velocity of the air current in metres per second (1 metre per second = 2·24 miles per hour). Hence if θ is known the velocity of the air current can be determined by taking the dry kata reading. This method, as has been already mentioned, is useful for measuring very low velocities, but breaks down with an alternating or badly eddying current. With low continuous currents an accuracy of 10% may be expected, as compared with only 80%–100% with an anemometer. The only method, then, is to supply heat at a known rate to the air current electrically; or to use a hot-wire anemometer. Further experiments gave the equation :—

$$H_w = H_d\,(0{\cdot}27 + 0{\cdot}49\,V^{0\cdot5}) + (0{\cdot}08 + 0{\cdot}10\,V^{0\cdot3})\,(F - f)^{\frac{4}{3}}.$$

where H_w is the wet kata cooling power, F = vapour tension of saturated air at 36·5° C., and f = vapour tension of the air observed. From this equation the cooling power due to evaporation only $(H_w - H_d)$ is seen to be represented empirically by $(0{\cdot}08 + 0{\cdot}10\,V^{0\cdot3})^{\frac{4}{3}}$. It may be noted that 0·26 metres per second was the lowest observed velocity, but the mean experimental results agreed well with this equation up to 4 metres per second (9 m.p.h.) which is more than concerns mine ventilating engineers.

These formulæ (with more places of decimals than are given here) are based on tests carried out by Dr. Leonard Hill for his papers before the Royal Society and for his book, *The Science of Ventilation.* The experiments were made chiefly at East London College. Subsequent experiments which agreed well with each other were made at the National Physical Laboratory in their 4 ft. and 7 ft. wind tunnels, and at Oxford with a rotating arm machine. These tests may be taken as more reliable than the earlier ones, and give :—

For velocities greater than 1 metre per second :—

$$H_d = (0{\cdot}13 + 0{\cdot}17\,V^{0\cdot5})\theta.$$
$$H_w = (0{\cdot}10 + 1{\cdot}10\,V^{0\cdot5})\theta'.$$

and for velocities less than 1 metre per second (200 ft. per minute) :—

$$H_d = (0{\cdot}2 + 0{\cdot}4\,V^{0\cdot5})\theta.$$
$$H_w = (0{\cdot}35 + 0{\cdot}85\,V^{0\cdot5})\theta'.$$

where $\theta' = (36{\cdot}5°\,C. - t')$, t′ is the wet bulb temperature of air in degrees centrigrade, and V equals the velocity in metres per second.

These two latter formulæ expressed in feet per minute and degrees Fahrenheit become :—

$H_d = (0\cdot 11 + 0\cdot 016\ V^{0\cdot 33})\theta.$
$H_w = (0\cdot 19 + 0\cdot 08\ V^{0\cdot 33})\theta'.$

It will be observed that with the aid of the above formula the wet kata cooling power can be calculated if the temperature, vapour tension, and velocity are known. In the case of surface conditions the prevailing wet kata cooling power could be calculated from the published meteorological records if the wind was steady and the effect of sunshine was neglected. The effect of depth or increased barometric pressure is naturally to increase the cooling power. The percentage change in cooling power is approximately one-fourth the percentage change in pressure. The formula which has been checked by experiment is :—

$$H_2 = \tfrac{1}{2} H_1 \left(1 + \sqrt{\frac{P_2}{P_1}}\right).$$

Conversely cooling power decreases with altitude. At the altitude of the Rand where the pressure is about 20% lower than at sea-level the cooling power will be but five per cent lower than at sea-level, an amount which can be neglected for most practical purposes, particularly as the formula only applies to cooling in still air. For the case of the Rand Mr. H. S. Ireland gives the modified dry kata formula as :—

$$\frac{H_d}{\theta} = 0\cdot 26 + 0\cdot 44\ V^{0\cdot 5}$$
$$\text{or } H_d = (0\cdot 26 + 0\cdot 44\ V^{0\cdot 5})\theta.$$

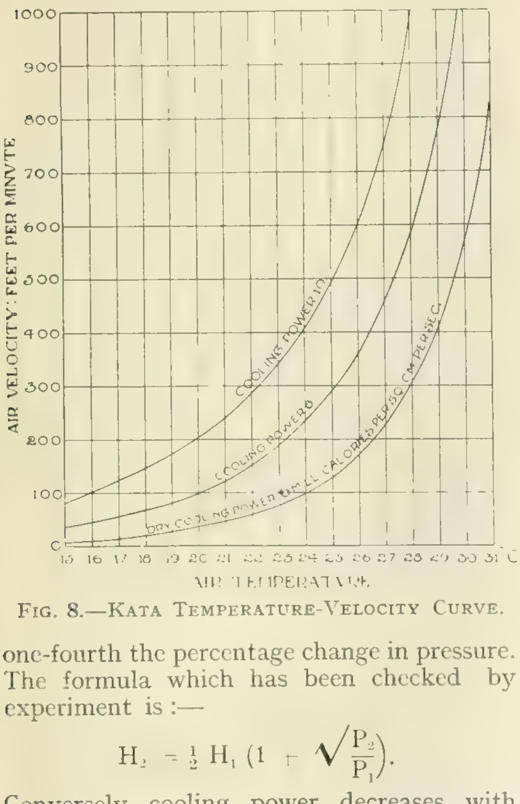

FIG. 8.—KATA TEMPERATURE-VELOCITY CURVE.

How cooling power varies with velocity and temperature is shown from the latest determinations in Fig. 8. Fig. 9 shows the curves connecting cooling power and velocity as arranged for the estimation of the latter.

APPLICATION OF THE KATA-THERMOMETER.—The most immediate use of the kata-thermometer in mining is for the purpose of investigating the cooling effect obtainable in hot mines from artificially produced air currents and the reduction of body clothing.

Mr. E. H. Clifford, in his paper on the City Deep (see Bibliography) shows what a useful guide kata readings may be when one has to deal with a saturated atmosphere. Kata readings do not give an exact index of physiological effect, but they do give actual cooling power, and that has been shown to be the chief factor influencing the capacity for physical work. On the City Deep a wet kata reading of 15 millicalories per square cm. per second was considered the lower limit for physical work, while 30 was taken as the upper limit. The best conditions for physical work without much clothing corresponded to a reading of 20. Wet kata readings were considered most because on this mine it is necessary to keep the air saturated for the purpose of allaying dust. The foregoing figures assume the absence of excessive velocity or excessive dryness, both of which are injurious, even though the wet kata

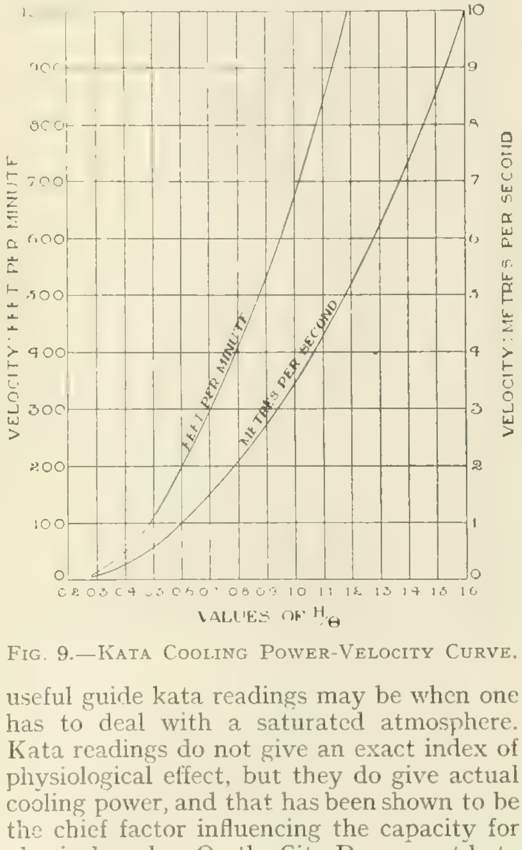

FIG. 9.—KATA COOLING POWER-VELOCITY CURVE.

reading be satisfactory. Where clothing is worn whether it be wet or dry profoundly affects the actual cooling power of any given air current on the body. With warm air this difference between actual and indicated cooling power is greatest with light wet clothing in dry air and least with no clothing in saturated air. Generally speaking, a wet kata reading of about 20 or a dry kata reading of about 10 indicates satisfactory conditions for physical work with little clothing. Dr. Leonard Hill gives dry 10 and wet 30 to 35 for manual work. Mr. H. J. Ireland finds 6 and 18 respectively sufficient for a slightly clothed native.

The basal metabolism of the average man when breathing 20 cubic feet per minute will correspond to a heat loss of about one millicalorie per square cm. of body surface per second. Waste may bring this up to three millicalories when breathing 60 cubic feet of air per minute. The rise of body temperature itself to about 102° F. during muscular exertion facilitates cooling considerably where conduction is relied on.

It is true that in the general ventilation of a mine a quantity of air sufficient to keep the mine at a low enough temperature must be supplied, as velocity cannot always be varied from place to place. But the kata-thermometer supplies the means of testing reliably where this velocity is too low or where the air has warmed up too much for efficient work as distinct from prevention of work. Such readings could well be marked on the mine's quarterly ventilation plan. An air current at nearly the same temperature as the body is far less noticeable than an appreciably slower one at a much lower temperature. This point is important in considering the comfort of the worker.

In the case of metal mines situated in places where considerable seasonal variation takes place in surface humidity and temperature and where the mine air is not saturated with moisture owing to the necessity for allaying siliceous dust, the kata-thermometer may be employed to effect great economies in the quantity of air required for efficient work. Owing to the comparatively few deep metal mines being worked as yet this has not been made the object of much study. The number of such deep mines must unfortunately increase greatly in the near future.

In such cases a continuous record of the cooling power of the air in the main levels might be found of value. For such purposes an instrument called a "Caleometer" has already been designed by Dr. Leonard Hill and Mr. O. W. Griffith. It is an electrical instrument which automatically measures as electrical energy the amount of heat energy required to keep a small coil of wire at body temperature, and, therefore, can record the cooling effect of the air current in which the coil is placed. (This instrument is made by Robert W. Paul, of the Newton Avenue Works, New Southgate, London, N.) The record of up to eight coils in different places can be taken on the same roll. For a record corresponding to wet kata readings the coil is surrounded by a tape hanging in a pot of water. The ordinary kata-thermometer is also made in a recording form by the same company.

Actual observation (Daniel Harrington) on the miners themselves has shown that a minimum air velocity of 25 ft. per minute is most desirable in even cool dry mines (dry bulb temperature of 75° F.) for efficient work, but that a velocity of 100 ft. per minute is required where the humidity is over 85%. In hot wet mines a velocity of over 500 ft. per minute may be required. It was found that men could work without inconvenience in velocities as high as 1,000 ft. per minute, and this in spite of an oxygen depletion of 1% (the air containing 20% oxygen instead of 21% as at surface) and a CO_2 content of 0·30% or more.

The utility of the kata-thermometer for checking such results is great, particularly where saturated air at about blood temperature has to be used and is circulated at high velocities by small fans and canvas tubing. A reduction of the relative humidity from saturation by even a small amount, say to 95%, renders the effect of velocity far more pleasant to the worker. The subject of retaining such a reduction without interfering with the allaying of dust was dealt with in the discussion on Mr. Clifford's paper before the Institution of Mining and Metallurgy (March, 1921), and is a matter which requires investigation more urgently the deeper and hotter our mines become. Such investigations are rendered far easier of prosecution by the invention of the kata-thermometer. In Mr. Harrington's paper (p. 21) on Ventilation and the Use of Small Fans (see Bibliography) this instrument does not seem to have been used. In another paper on the use of booster fans where the air was above blood temperature, the wet bulb temperatures were taken as the index of cooling effect and

the volume of air necessary to keep down this temperature was measured. The amount found necessary was 600 cubic feet per man per minute, instead of the 400 cubic feet used elsewhere in the mine. Of course, where the general, as distinct from the local, ventilation of a wet mine is increased, a slight reduction of temperature is caused by the concomitant increase in the quantity of water evaporated underground to give a saturated condition of the air. Only 0·30 grm. is required to cool one cubic metre of air 1° C. Mr. C. Mezger gives the following example to show the order of effect to be expected from this cause. Assuming the temperature at bank and shaft-bottom to be respectively 10° C. and 19·5° C., and the saturation 90% in both cases, the absorption of moisture per cubic metre of air will be 6·6 grammes consuming 3·96 calories: the temperature will therefore be lowered 13·2° C. Auto-compression in the shaft and friction and conduction throughout the mine have a warming effect. Therefore the actual reduction in air temperature is naturally less than the calculated fall. The effect on the body of air temperature (but still more of velocity) is, of course, modified by clothing as it hinders both evaporation and conduction. This can be investigated quantitatively by the kata-thermometer. The instrument, with a light wire shield, can readily be placed between the skin and the clothing of a man. The heat loss of the human body lightly clothed is approximately one-sixth of the dry kata cooling power where this is normal, and is about 60% of the heat loss of the naked body. In estimating the total heat loss advantage may be taken of the empirical rule: surface in square metres $= 0{\cdot}123\,W^{\frac{2}{3}}$ for men where W is the weight in kilogrammes, but the subject is a rather complicated one. In Chapter VIII, Vol. II, of *The Science of Ventilation*, Dr. Leonard Hill gives a summary of the present knowledge on this subject, but in the case of hot and deep mines it may be assumed generally that for manual work clothing will be discarded.

In connexion with the subject of kata cooling powers interesting tests have been carried out (Zuntz) on the amount of water vapour (perspiration) lost from the body during exertion. In tests on a number of fully equipped men in uniform the thinnest only lost 953 grammes, while the fattest lost 2,575 grammes of moisture. Taking 800 grammes loss per 1,000 calories expended in saturated air at 50° F. as the standard, the amount was diminished 4 grammes for each 1% reduction in dryness and 70 grammes for each unit increase in wind velocity (on a scale of ten units). A rise in temperature increased the loss by only 0·2 grammes per degree Fahrenheit.

These tests confirm the importance of velocity as shown by the kata-thermometer, but also show that at moderate temperatures training has a far greater influence than either humidity, velocity, or change in temperature. This is curious considering how many a good old Cornish miner is not exactly slim. Still, fatness is partly a thermal reserve for heavy work, and is not entirely due to lack of fitness. A normal man carries about 18% of fat, which on a weight of 11 stone corresponds to a thermal reserve of about 12,000 calories, three days full food supply.

As temperature increases the influence of humidity and velocity on perspiration becomes greater in proportion, so that the taking-off of clothes is essential in hot places in order to obtain full advantage of the ventilation. Where cooling by conduction and convection has to be relied on this is even more necessary, as the clothes hold a layer of insulating air in contact with the skin. (See *Science of Ventilation*, Vol. II.) Different materials act differently in this respect.

Application of the Ergometer.—With regard to the individual efficiency of work performed in hot and deep mines, the working efficiency of the miner is not only affected by the temperature, velocity, humidity, and composition of the air in which he works and by the approximation to optimum effort which he exerts and by the amount and condition (wet of dry) of his clothing, but also by his fitness and stamina, as influenced by his health, general hygienic conditions, diet, acclimitization, physical training, and individual idiosyncrasy. Interest in the work, contentment, and an adequate wage, combined with the absence of any artificial enhancement of his standard of living (for instance, meat, boots, and bicycles for Kaffir boys) are also necessary factors. The length of time worked underground and the number and duration of rests during the shift also affect the efficiency on a given output.

Of the above factors only those dealing with adequate ventilation can be measured with the kata-thermometer. The remaining factors at first appear hopelessly numerous and diverse, but their sum total effect can be estimated by means of measuring the

mechanical efficiency of the man and his degree of liability to fatigue. Fatigue is here used in the medical sense to mean that condition of the body which results from too heavy a demand for physical work having been made on it, that is a load which has caused an additional consumption of actual nitrogenous muscular tissue as distinct from a mere oxidation of the stored fat and

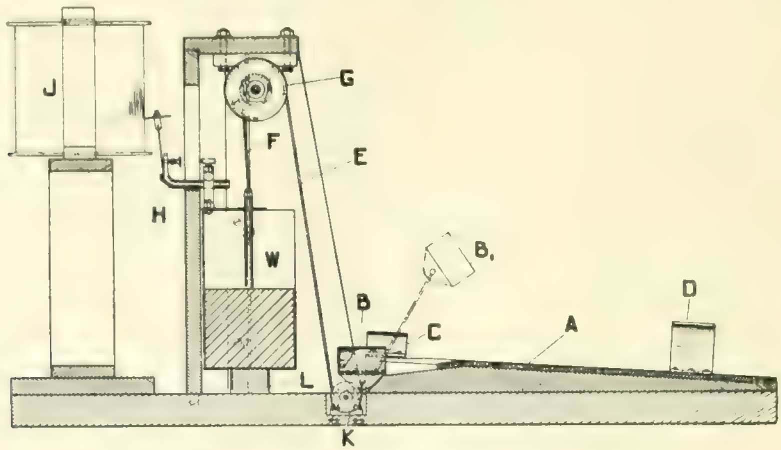

FIG. 10.—ERGOMETER FOR MUSCULAR FATIGUE

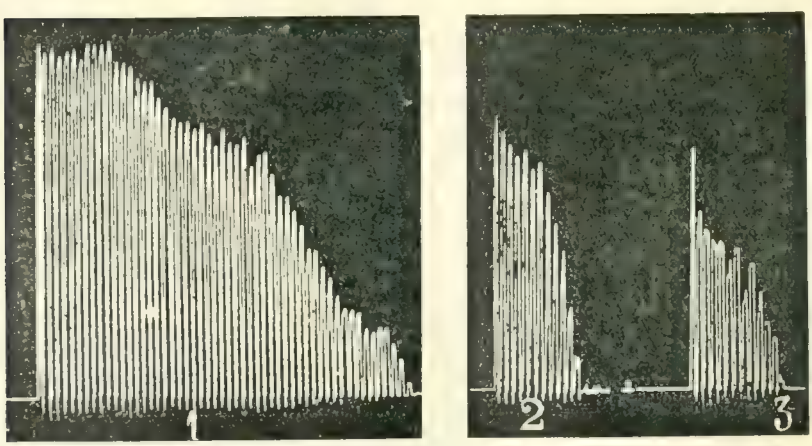

FIG. 11.—ERGOGRAPHS.

carbohydrate (glycogen). Nervous fatigue, the saturation of the blood with CO_2, and the production of lactic acid and other deleterious substances in the blood from only partially oxidized tissues are other physical accompaniments of fatigue. When fatigue has commenced a man is positively unable to work at his proper efficiency, and his expenditure of physical and nervous energy on a given amount of work increases continuously. If rest, sufficient to allow for the restoration of the purity of the blood, is not allowed, general fatigue results, which affects the whole body and may even cause death. Dr. Orenstein says the chief results of over-fatigue " are lassitude, loss of mental alertness, craving for stimulants, decreased resistance to disease, increased liability to chill, nervous irritability, discontent, and an enormous lowering of efficiency in the performance of work."

Hence the determination of the conditions causing fatigue must go hand-in-hand with determinations of mechanical efficiency, and are particularly important in determining the fitness of a man for special exertion, as in mine-rescue work or hand-drilling.

An absence of protein in the diet is one cause of fatigue. Protein was for long

regarded chiefly as a fuel for the muscles, and 100 grammes ($3\frac{3}{4}$ oz.) per day was laid down as the minimum necessary. Its function is really to replace worn muscular tissue. It has been shown (Cathcart, 1912, p. 109) that so long as the task does not result in excessive fatigue (overload) no *increase* of nitrogen content can be detected in the urine as due to such work, although it has often been stated that the nitrogen content of the urine is proportional to the amount of work done. Hindhede (1913), of the Nutrition Institute of Copenhagen, carried out observations on a man (11 stone in weight) who worked as a mason and labourer for 95 days on a diet containing only $1\frac{1}{2}$ oz. of protein equivalent to only 170 calories out of a total of 5,000 calories, the energy value of his daily diet. Its "specific dynamic energy" certainly makes a larger ration desirable, but such a ration does not prevent an increase of the nitrogen content of the urine being used as an index of overload on the human machine, nor make the nitrogen content proportional to the total work done.

The most direct method (Fig. 10) of determining muscular fatigue (see Mosso's book on Fatigue) is by the use of ergographs or charts showing the time taken to completely fatigue a given set of muscles by repeatedly contracting them, and also showing the relative force of the contraction for a given amount of energy in each contraction. In Fig. 11, it is seen that fifty-two contractions were performed before the muscles were completely fatigued. Two hours were required for complete recovery. If only half the number of contractions had been performed the muscles would have required but one-quarter the time to recover; moreover, the amount of work performed would have been not half, but approximately two-thirds of the whole (see Dr. Orenstein's paper). The application of such results to manual labour problems is obvious. The acceleration of fatigue by rise of temperature can also be tested in this manner, but such results give local not general fatigue, and do not indicate the degree of mechanical efficiency.

From what has been said earlier in this article, it might be expected that increased consumption of protein would also be indicated by a fall in the R.Q., and that this fall would afford an index of fatigue, but this is masked in practice by a quite large drop in the CO_2 content of the expired air, due to the lung ventilation being incapable of supplying the increased demand of the over-loaded human machine for oxygen, and also due to the dilution of the expired air by hard panting. On normal heavy loads oxygen-want causes quick and rather shallow breathing, owing to the effort to get an increased volume of air into the lungs. Similarly on overloads in normal air oxygen-want causes the same effect. A high atmospheric content of CO_2 on normal loads, be it noted, causes deep, slow breathing, due to the effort to obtain greater pulmonary ventilation.

It is for these reasons that plotting the percentage of CO_2 in the exhaled air against load gives such useful results when the ergometer is being used in conjunction with determinations of the Respiratory Quotient for estimating the mechanical output and efficiency of an individual.

The percentage of CO_2 in exhaled air increases with the load from about 4% up to about 7% on full load; if the load be increased further the percentage of CO_2 falls for the reasons already mentioned. Hence, on plotting the results obtained for a given individual a dome-shaped curve is obtained. (See Fig. 12, next page.) The rate of doing work indicated at the crest of this curve makes the change from load to overload and the commencement of fatigue; that is, the man can sustain loads up to the crest load for some considerable time, as his oxygen input is adequate to deal with such rates of work, but he can only bear loads slightly above the crest value for a short period. (Second Mining Rescue Apparatus Report, p. 55.)

The most remarkable thing about such curves is the striking way in which they show not only the strength and the stamina (power of supporting sustained physical effort) of a man, but also his degree of fitness (physical training for heavy work). This latter is arrived at by testing the man with both ordinary and oxygen-enriched air. When ordinary air is breathed during exertion the man in good physical training exhales a higher percentage of CO_2 and a lower percentage of oxygen, and also breathes less air for a given consumption of oxygen or output of work than does the man in bad training. The fit man not only works at a higher food efficiency, but, on a given load *more completely utilizes* the air he breathes. But when he is tested with enriched air he shows but little increase in the CO_2 content of his flue-gases. In fact, enriching the

oxygen above 60% seldom gives any advantage at all with a fit man.

A man who is in bad training, on the other hand, immediately responds on load to enrichment of the air supply, and on pure oxygen almost catches up the trained man, so far as his thermal efficiency is indicated by the percentage of CO_2 expired. The crest load of a man on ordinary heavy work (4,800 ft.-lb. in Subject I and 6,400 in Subject II, Fig. 12) is sometimes expressed as a percentage of 10,000 ft.-lb., an arbitrarily chosen crest load, and called his percentage fitness. This is a purely relative figure. A more useful method of expressing the fitness of a subject is to divide the crest ordinate of the air-curve by that of the oxygen curve, 3·75% CO_2 being chosen as the datum level

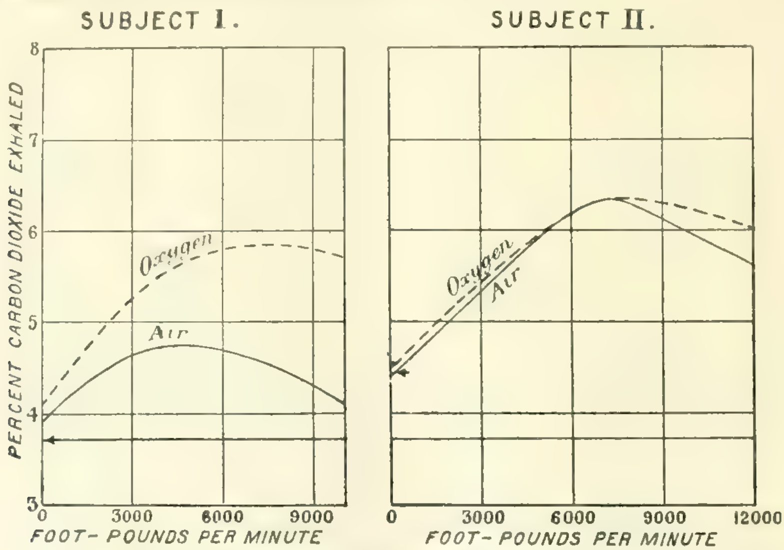

FIG. 12. ERGOMETER CURVES

from which to measure. By this method the fitness of Subjects I and II are 46% and 100% (a sedentary person and a specially selected instructor in physical drill respectively) instead of 50% and 70% by the arbitrary method. By the former method the fitness of a healthy working miner is generally about 75% (Briggs). This method of measuring fitness by physiological response to oxygen during muscular exertion really tests the fitness of the lungs alone. Where these are fit the rest of the body is generally fit, but apart from this the test is particularly valuable in mine-rescue work and in determining the fitness of a man for work in high altitudes or at great depths.

With regard to the thermal efficiency of the human machine, as distinct from fitness, determinations with the cycle ergometer by Professor Henry Briggs give a figure of about 23% crest efficiency for average citizens, and 33% for fit, trained, manual workers; 37% is his highest recorded figure. The average of Professor Langelois' determinations in France is about 33%, while Benedict and Cathcart got about 33% quite independently in America. This is a high figure compared with a steam engine at 12%, but the human machine cannot maintain crest loads for 24 hours a day. The steam-engine, on the other hand, requires no sleep.

Professor Waller and Miss G. de Decker have gone somewhat further (see Bibliography), and have investigated the physiological cost of muscular work in various different industries, and the calories consumed per square metre of body surface per hour on both piece work and time work.

Determinations on the cycle ergometer, combined with observations of the R.Q., may thus be most useful in mining work for testing not only the strength of a man but also his capacity for heavy exertion and the amount by which his output can be increased by training. The value of such tests for men in the Army has been recognized in France, where tests are made on the capacity of men to march at varying speeds with different weights of equipment in flat and hilly country. A travelling escalator belt, whose inclination and speed can be varied, is used so that the man marching

remains at a constant distance from the CO_2 recorder (Professor Langelois).

In mining, working efficiency tests, as mentioned, already find a use in testing men for mine-rescue work and for work at high altitudes. The greatest practical use for such tests seems to be on the one hand for determining the effects of diet, training, depth, temperature, and adequate ventilation on the working efficiency and stamina of selected men, particularly with a view to employment in hot and deep mines, while, on the other hand, such tests should be useful in testing the efficiency and fitness for mining work of freshly recruited white labour and of natives from new areas. The old method of trial by death rate on large batches of native labour recruited from new areas is, at times, troublesome and expensive.

A study of the amount of effort expended is the first step after hygienic conditions have been obtained, then the optimum effort and the rests and amount of work per shift. After that comes the basic economic question: does the human machine pay better than electricity or compressed air under the given circumstances ?

One of the simplest cases in which it does not as a rule pay is that in which the human machine is used instead of mechanical haulage for taking men to and from their work in deep mines. It is for the mining engineer to decide this.

In the words of one of our greatest pioneers in this new branch of mine engineering, the effect of physical conditions on human working efficiency: "It is felt that both the apparatus and the theories have reached a stage of development in which they can be presented to the mining world for verification and modification."

Bibliography.

Herewith is a list of books and papers that may be consulted in studying this subject. Papers particularly useful to mining men are marked with an asterisk.

The Human Machine.

*The Human Machine. By Professor Henry Briggs, A.R.S.M. The Mining Institute of Scotland, February 5, 1921. Reprinted in the *Colliery Guardian* for February 11, 1921, p. 413. Discussion, October 14, 1921, p. 1,072.

*The Respiratory Exchange of Animals and Man. By A. Krogh. Longmans, 7s. 6d.

The Physiology of Protein Metabolism. By E. P. Cathcart. Longmans, 7s. 6d.

Oxidations and Reductions in the Animal Body. By D. D. Dakin. Longmans, 7s. 6d.

Principles of General Physiology. By W. M. Bayliss. Longmans, 30s.

Reports of Industrial Research Board. By Professor Waller. For the latest of these see the *British Medical Journal* for May 7, 1921, p. 669.

"The Oxidases and other Oxygen Catylists concerned in Biochemical Oxidations" By J. H. Kastle. Bulletin 59, Hygienic Laboratory, Public Health and Marine Hospital Service of U.S.A.

Physiological Economy in Nutrition. By Russel H. Chittenden, 1905. Heinemann.

*The Physiology of Industrial Organization. Professor Jules Amar. The Library Press, 30s. Reviewed in *Engineering*, January 3, 1919, p. 21.

Effects of Oxygen Deficiency on Small Animals and Men. Technical paper No. 122. Bureau of Mines, Department of Interior, U.S.A., 1915.

The Ergometer.

*Second report of the Mine Rescue Apparatus Committee, 1920. H.M. Stationery Office, 2s.

*A Contribution to the Study of Mine Atmospheric Conditions on Fatigue. By A. J. Orenstein and H. J. Ireland. *Journal* of the South African Institution of Engineers. Vol. xix, March, 1921, p. 126, and Vol. xx, October, 1921, p. 44.

Mine Rescue Work. By H. F. Bulman. Crosby Lockwood. 12s. 6d.

Testing the Human Machine. *Scientific American*, September, 1921, vol. 125, p. 187.

Ventilation.

*Reports of the Committee on the Control of Atmospheric Conditions in Hot and Deep Mines. First report, Inst. Min. Eng., April, 1920, p. 231. Second report, June, 1920, p. 323. Third report, June, 1921.

Metal Mines Ventilation. *Engineering*, August, 1920.

Ventilation in Metal Mines. By D. Harrington. *Engineering and Mining Journal*, April 30, 1921, p. 735.

The Cooling Effect of Ventilating Current. By C. Hezger. *Colliery Guardian*, July 22, 1921, p. 235.

*Ventilation in Metal Mines. By D. Harrington, Bureau of Mines, Department of Interior, U.S.A. Technical Paper, No. 251, 1921.

The Kata-Thermometer.

*The Kata-Thermometer and its Practical Uses in Mining. By H. J. Ireland. *Journal* of the Chemical, Metallurgical, and Mining Society of South Africa. Vol. xxi, November, 1920, p. 84.

*The Science of Ventilation. By the Medical Research Committee (Dr. L. Hill). H.M. Stationery Office. Vol. i, 1919, 10s. ; vol. ii, 1920 (Theory), 6s.

*Report on Ventilation and the Effect of Open Air and Wind on the Respiratory Metabolism. Local Government Board, 1914. H.M. Stationery Office, 9d.

Dr. Leonard Hill's paper in the Phil. Trans. Royal Society. Series B, vol. ccvii, pp. 183–221, or separately as B. 339, price 3s. See also "The Effect of Velocity on Cooling Effect," pp. 198-203, and "Heat Loss at Body Temperature by Convection, Radiation, and Evaporation."

The Kata-Thermometer [illegible] September 1?, 1921, p. 387.

*Some [illegible] work in the City Deep Mine at a depth of 7,000 ft. By E. H. Clifford. Institution of Mining and Metallurgy, Bulletin 197, February, 1921; Discussion, Bulletin 198, March, 1921.

The Comfort Meter Leaflet. Given by James J. Hicks, of 8, Hatton Garden, E.C., with the Kata-Thermometer, when purchased.

In the foregoing works various useful references to the *Journal of Physiology*, the *American Journal of Physiology*, the *Proceedings* of the Physiological Society, the *Proceedings* of the Institute of Hygiene, and the *Year Book* of the Carnegie Institute, will be found. A short bibliography of the subject is given by Dr. Leonard Hill in the Philosophical Transactions of the Royal Society already quoted.

Among the chief actual workers on this subject are Dr. Leonard Hill, F.R.S., of the Medical Research Council, Professor Henry Briggs, D.Sc., A.R.S.M., of Edinburgh, Dr. J. S. Haldane, F.R.S., of Oxford, Sir John Cadman, of Birmingham University, Professor E. P. Cathcart, D.Sc., of Glasgow, Professor Waller, of the University of London (The Industrial Research Board), Professor Martin, of the Lister Institute, and Professor Macdonald, late of Sheffield, now Professor of Physiology at Liverpool. In America Professor F. G. Benedict and Dr. W. Atwater have done much laboratory work on this subject at the Carnegie Institute, Boston, for various United States Government Departments.

The pioneer workers on the application of this work to metal mines are Dr. A. J. Orenstein, C.M.G., M.D., etc., and Mr. H. J. Ireland, M.B.E., B.Sc., of the Transvaal Chamber of Mines.

New papers by any of the above authors on the subject of Ventilation and Efficiency can be relied on to be of interest to mining engineers.

BOOK REVIEWS

Concentration by Flotation. Compiled and edited by T. A. Rickard. Cloth, octavo, 690 pages, illustrated. Price 42s. net. New York: John Wiley & Sons; London: Chapman & Hall, Ltd.

Just as there have been continual legal and commercial disputes about flotation, so have there been plenty of antagonistic views among writers in the Press and among compilers of books, when dealing with this subject. Most of the literature so far made accessible to the public has come from the United States or from American authors, and the views expressed and the information given by these writers are almost always unfavourable to the status of Minerals Separation, Ltd. This company has secured the validity of its patents in all the courts of the world, after very lengthy arguments, so that *ex parte* statements in the Press and in books with regard to the history of the invention no longer really serve a good purpose. On the other hand, the fact that Minerals Separation exercises its monopoly to the fullest extent allowable by law, naturally raises considerable opposition and ill-feeling among its past and present enemies, so that post-patent agitation arises urging that the possession of such a monopoly is contrary to public policy. It is also questioned whether the ownership of patents by a corporation which means to derive its benefits entirely from licences was contemplated when the original patent laws were drawn up. Thus the opponents of Minerals Separation would wish to put the company in the position of Shylock, who is first told that the "law allows it and the court awards it," and afterwards is informed that if he, an alien, attempts to collect his dues, he will be outlawed for conspiring against the worthy citizens of a great State. No doubt in many quarters there is an outcry against the business and legal methods of Minerals Separation; but after all the law is on its side, and that not through any accidental circumstance.

We have said that most of the literature on flotation comes from the opposite camp. Much of it is published with the intention of belittling the claims of the patentees to greatness; some is published to give helpful information as regards both practice and theory; and some is obviously intended to draw discussion and obtain records of experience from other investigators. It is a pity, of course, that Minerals Separation does not allow its engineers, chemists, and physicists to write articles for the Press and to publish records of experiments and authentic accounts of the origin of the various improvements in the process, for thus many lacunæ would be filled and there would be a variation in the atmospheric effects. King John and Louis XI suffered in the estimation of posterity because they allowed

their enemies to write the history of their times without protest or counterblast; in the same way Minerals Separation takes no steps to tell the true and full inside story of the development of flotation.

Thus it comes about that we have a book on flotation, edited and compiled by Mr. Rickard, which is like the play of *Hamlet* without the Prince of Denmark as one of the characters. There is a vast amount of history, theory, and practice in its pages, but being written without the aid of the chief inventors and investigators there are many places where the information is incomplete and even inaccurate. Moreover, the arguments and the interpretation of the history are admittedly and obviously hostile to Minerals Separation and its technical staff. If the reader bears the foregoing remarks in mind he will find much useful aid and help in the pages of the book. It must also be mentioned that as the book consists of a reprint of a great variety of articles by many authors published in the *Mining and Scientific Press* during the years 1915 to 1920, the quality of the reading matter is variable, and separate sections are occasionally contradictory, no attempt having been made to co-ordinate or reassemble the subject matter of the articles.

In all forty articles have been reprinted in this book. Of these eight are contributed by Mr. Rickard, while other well-known names in the list of contributors are Ralston, Glenn Allen, Clennell, Hebbard, Shellshear, Henderson, Evan Simpson, and Coghill. Mr. Rickard writes on the history of flotation, the principles of flotation, and flotation litigation. He also contributes descriptions of practice at Utah Copper and of the smelting of flotation concentrates at Garfield. There are articles on testing ore for flotation, the disposal of flotation residues, the flotation of oxidized ores, the Bradford process, the Horwood process, the flotation of silver ores, the cyanide treatment of flotation concentrates, and several others of similar practical character. The remaining papers deal with the theory, and this section of the book is the weakest.

To proceed now to a few details that deserve criticism. In the first place the glossary at the beginning of the book is quite unworthy of the subject, and the reader is apt to wonder whether the errors are due to ignorance or to blunders on the part of the stenographer and the typist. It is surely not necessary to define such words as buoy, skin, scum, agitation, emulsion, molecule, grease, froth, pulp, metallic, gangue, bubble, fat, and film. With regard to "skin," this word is said to be derived from the Anglo-Saxon "scinn," ice. The word "ice" has been copied from an etymological dictionary, and should be "Ice.," which is a contraction for "Icelandic," and evidently refers to the remainder of the quotation from the dictionary, which has been lost during its transmission to the glossary. The definition of oleic acid given in the glossary says that it is the "fatty acid contained in olive oil combined with cresoline." Presumably "cresoline" should read "glycerine," but even so olive oil is not combined with glycerine. Then, again, the word "flotation" is said to be derived from the French "flottaison," the meaning of which is given as "water-line." This is not the meaning of the French word. Anyway the English word was not derived from the French, but was invented at home.

When we get to the definitions of the more technical words such as colloid, adsorb, surface-tension, and gel, all we need say is that most physicists will not agree to the wording.

In Mr. Rickard's history of flotation we miss any reference to Jason's expedition to capture the Golden Fleece, which is generally held to indicate the accumulation of gold particles on sheep-skins placed in the auriferous rivers of Asia Minor during flood-time. Then, again, it is impossible to accept the statement that it is due to the "patient empiricism of Hoover, Callow, and other technicians" that flotation was developed as a workable process, for, as a matter of fact, Mr. T. J. Hoover was engaged by Minerals Separation some time after the process had been proved to be a success, while Mr. Callow only appeared on the scene in 1913. If the expression "and other technicians" had been expanded, and the names of, say, Moulden, Hebbard, Chapman, Bradford, Horwood, Broadbridge, and Shellshear had been added in front of Hoover and Callow, the real case would have been presented. Another statement in this section of the book to which exception may be taken relates to the origin of the slide machine used in testing. Mr. Rickard says that this "machine was designed by Hoover and perfected by many others." As a matter of fact, the machine was designed by Mr. Sulman, and the first was made by Mr. Picard before Mr. Hoover had any

connexion with flotation. This original machine was exhibited in evidence during the litigation in the United States.

As has already been said, the sections of the book devoted to the theory and physics of flotation are the weakest. Here we miss any article by Dr. Wilder D. Bancroft, who knows more about the subject than anyone else in the United States. There are brief references to Dr. Bancroft's evidence against Minerals Separation in the American litigation, but a summary of his evidence, or, better, a special article by him, would have added greatly to the value of the book.

The theory of flotation demands an extensive acquaintance with the most intricate problems in physics and chemistry, and as the articles on flotation in the volume under review have not been written by trained physicists, a high standard of accuracy could hardly be anticipated. For the most part they have been written by authors who are groping after an elementary knowledge of the scientific aspect of the question. Perhaps the best paper is that on "Molecular Forces and Flotation," by Coghill, but much of this article is devoted to exposing fallacious statements which could scarcely be entertained by anyone conversant with the fundamental laws of physics. It is noticeable that Coghill gives a fairly accurate account of the mechanism involved in the flotation of solids denser than water at the surface of water; his explanation serves to show that these particles do not float by adsorption.

Anderson's paper contains a number of mis-statements, a few of which may be mentioned. On page 286 it is stated that "a bubble of air is spherical in shape, and this shape can only be maintained if the external pressure exceeds the internal pressure." The reverse is the fact; of course, the *internal* pressure must *exceed* the external. On page 278 it is stated that "all acids will lower the surface-tension of water." Röntgen and Schneider have found that as the concentration of sulphuric acid in water increases the surface-tension rises, until the liquid contains about 48% of acid, and then decreases as the concentration of the acid increases. A 70% solution of sulphuric acid in water has a surface-tension almost identical with that of pure water. This statement is not a mere slip, as the action of acid is likened to that of oil on page 279.

Hardy Smith's paper contains many wild and misleading statements. The statement (page 269) that "the surface of the liquid in contact with the particle must be considered as tending to have surface-tension, although the tendency is opposed by the adhesion" is really quite incomprehensible, although Hoover's book on Concentrating Ore by Flotation is quoted in support. The statement (page 271) that contaminating agents are added so as to counteract the difference in vapour pressures of large and small bubbles in order to prevent them from coalescing, has also no foundation in fact; a contaminating agent will reduce surface-tension of a bubble and so slightly reduce the pressure of the gas contained therein, but its effect on vapour pressure is negligible. The statement that the surface-tension becomes zero at the boiling point (page 273) is, of course, quite inaccurate, and is contradicted by Coghill on page 302. On page 275 we find the statement: "As soon as a bubble has expanded to an appreciable size, the vapour pressure of the liquid is in excess of that necessary to balance the surface-tension, and the bubble expands so rapidly that it literally explodes." No such explosion occurs, and the vapour pressure of the liquid has nothing to do with the stability of a bubble. On page 274 diagrams are given showing mineral particles enclosed in bubbles just as they might be in glass bulbs; elementary observation shows that such conditions never occur.

Mr. Rickard's article on the Principles of Flotation contains several very questionable statements. There can be no doubt that the surface layer of a liquid, instead of being denser than the rest of the liquid, as stated on page 57, is really less dense. The statement (page 61) that, when an alcohol is added to water, the change of viscosity enables a froth to be formed, cannot be supported. The stability of an armoured bubble (page 63) is not due to viscosity. This can be understood best by a simple analogy. It would be impossible to build a bridge using only liquid cement, but, by the aid of stones, the building of the bridge is rendered easy. The statement, page 73: "Any substance that will lower the surface-tension of water and be adsorbed by mineral particles would appear to promote flotation" is not correct; some substances, such as tannic acid, do both, with the result that flotation is rendered impossible. It is stated on page 75 that "the needle that floats on tap-water will sink in distilled water; although contaminants have lowered the

surface-tension of tap-water, it has more sustaining power on account of its aeration." As a matter of fact, a needle will float on distilled water, if this is not contaminated by grease, as often is the case, and the surface-tension of tap-water is not lower than that of distilled water; finally, the sustaining power derived from aeration is a myth. On page 77 is found the statement: "No longer is the mineral supposed to be buoyed by the bubbles, as if tied to a cork, but the minute particles of mineral are believed to be drawn into the bubble film." This statement is in direct contradiction with the explanation given by Coghill; it also involves a still more fundamental fallacy. In a footnote on page 76 it is stated that the layer of liquid subject to surface-tension has a thickness less than the radius of molecular action, and the "bubble film" mentioned by Mr. Rickard obviously refers to the layer subject to surface-tension. Various estimates of the radius of molecular action have been given, and these vary between 10^{-8} cm. and 10^{-6} cm. According to Langmuir's recent theory the layer responsible for surface-tension is only one molecule thick. Taking, however, the largest estimate of the thickness of a surface-layer, namely 10^{-6} cm., the diameter of a slime particle that could pass through a 200-mesh screen would be about five thousand times as great as the thickness of the bubble film into which it is believed to be drawn.

Instances such as those given above could be multiplied, but, without going further, it will be conceded readily that explanations involving so many mis-statements of fundamental principles which could have been avoided by reference to ordinary text-books on physics are not likely to carry much weight.

☞ Copies of the books, etc., mentioned under the heading "Book Reviews" can be obtained through the Technical Bookshop of *The Mining Magazine*, 724, Salisbury House, London Wall, London, E.C. 2.

NEWS LETTERS

PERTH, W.A.

October 20.

OIL IN KIMBERLEY DISTRICT.—Much has been heard of the discovery of indications of petroleum deposits in Kimberley district, in the north-east section of West Australia. A statement has been made on this subject by Professor Sir Edgeworth David, who has recently been making investigations. This statement is the first connected and reliable account of what is going on, and, moreover, it discusses the find in conjunction with other investigations elsewhere in Australia. It is therefore worth quoting in full here.

The area so far preliminarily tested is at Price's Creek, to the east of the junction of Christmas Creek with the Fitzroy River. This is approximately 200 miles south-west of the area where the asphalt glance has been found, and about 160 miles in a direct line south-east from Derby, and roughly 250 miles south-west from Wyndham. At Price's Creek indications of oil are now forming in small seepages which yield a distinct smell of petroleum. At one spot on the Rough range in this vicinity the grass will not grow on account of the oil seepage.

While Mr. Blatchford was at Price's Creek Mr. Freney had a bore put down by hand on the adjacent hill to a depth of 90 ft. Mr. Blatchford watched closely the minutest details of this boring, and collected all the samples and brought them under seal to Perth. There they were tested by Dr. Simpson, who found that true mineral oil was present, although in small quantities, the proportion increasing slightly with depth. The mineral oil is there contained in sandstone and thin limestone. The actual weight of the oil compared with that of the rock is only one part in 4,000, but this relatively small amount should be sufficient to supply quantities which under favourable conditions for concentrating and observation may be sufficiently extensive to be of economic value.

As regards the structure of the Kimberley oil-bearing region, Mr. Blatchford's observations and reports show that broad gentle arches exist over a very wide area in this district. For example, at Mount Wynne, which is about 100 miles west-north-west of Price's Creek, there is an anticlinal arch upon which is situated a hot spring, with a temperature of about 110° F., yielding continuous bubbles of gas. It is not yet certain that this is oil gas, but it is certain that the anticlinal structures extend throughout the whole of the area between Price's Creek and Mount Wynne. Tests are being made of this gas.

As regards the geological age of the strata at Kimberley which have yielded traces of oil and asphalt, Mr. Blatchford considers

that they are of Lower Carboniferous age, that is, of an antiquity greater than that of the coalfields of Newcastle, Irwin River, the Collie, and so on, and probably at least six times as old as the water-bearing strata in the great artesian basin of Central Australia. In this latter basin at Roma, Queensland, a considerable volume of natural gas has been evident at intervals for many years past. Mr. Henderson, the Government Geologist of that State, has said that while the bulk of the gas is methane, there is also present some gas derived from petrol. Mr. Cameron, the Assistant Government Geologist there, has spent some time investigating the question, and he is strongly of the opinion that there is oil under Roma. The gas, however, was tapped at a depth of no less than 3,700 ft. below the surface, and as artesian water in considerable volumes was struck at a higher level, it was found extremely difficult to materially reduce the great pressure of water in this bore so as to admit of the gas forcing its way to the surface without hindrance. If oil really exists in this region, and the pressure of the gas is insufficient to lift a column of water 3,700 ft. high, it will be necessary to take measures to seal off the artesian water in future boring, so that the gas may be allowed to rise.

Expressed in terms of actual years, the Roma deposit may date back to the order of something like 50 millions of years ago, while that of Kimberley would be at least 300 millions, but the great antiquity of this area does not preclude the possibility of oil occurring in probably payable quantities. In North America and Canada large important oilfields are found in rocks not only of the Lower Carboniferous age like those of Kimberley, but in even older rocks such as the Devonian, Silurian, and Cambrian, while the indications at Kimberley, both as regards the genuine mineral quality of the oil and the structure of the rocks containing it, appear to be quite feasible.

To judge by the reports of Mr. Maitland and his officers, the public may be cautioned against assuming that necessarily there will be a payable oilfield in that region. In many parts of the world, for example in New Zealand and Papua, even stronger indications of oil have been known to exist for some scores of years, and yet up to the present all attempts to work these deposits successfully have failed. In the case of Papua there is no question that there exists a continuation eastwards of the great oil belt, only perhaps about a tenth as old as that of Kimberley, which runs from Burma through Sumatra, Java, Borneo, and Timor to Dutch New Guinea and Papua. There are numerous actual oil-bearing springs and oil-gas wells in Papua. According to Mr. Blatchford's examination the Kimberley region is far more settled in its structures than that of Papua and so should have the advantage over the latter region.

The next step to the possible development of Kimberley should be an immediate careful geological survey to locate at once the most favourable anticlinal arches for prospecting operations. Many oilfields have been given a bad name through hasty prospecting in wrong places. So soon as this survey by competent geologists shows the most favourable lines for boring, bores should be put down, and a plant provided capable of drilling to considerable depths. If necessary, the boring should go to some thousands of feet. The discovery at Kimberley, so far as is known, is the first recorded occurrence of true mineral oils in Australia, and while caution is needed, the prospects from a geological point of view appear to be distinctly encouraging. If payable oil is struck there anywhere, it will probably be found to extend over a considerable area.

Further interesting and encouraging information regarding the prospects of discovering mineral oil in the North-West is contained in an interim report by the Assistant Government Geologist (Mr. T. Blatchford) on what is known as "Oakes's Find" in North-East Kimberley, which was laid on the table in the Legislative Assembly on October 11 by the Minister for Mines, Mr. J. Scaddan. After explaining at the outset that Oakes's Find is situated about half a mile up the Negri River from the junction of that stream with the Ord River, about 1½ miles down stream from the spot where the Ord River Station–Wyndham Road crosses the Negri, the report proceeds to deal extensively with the geology of the neighbourhood. Later, Mr. Blatchford points out that the find was first brought to departmental notice by Mr. Oakes forwarding samples of glance pitch. That discovery, says Mr. Blatchford, is certainly the most definite surface indication of mineral oil residue that has been found in West Australia. There is every reason to believe, he says, that the pitch has come in the form

of mineral oil from unexposed underlying beds, which has, by a process of inspissation, left the pitch residual behind filling the cavities in the rock through which it has migrated. The question now is to ascertain whether the oil still exists, by means of a systematic survey.

TORONTO

November 9.

PORCUPINE.—The mine managers have for some time been anxiously considering the power situation, fearing a repetition of the experience of last winter, when operations were greatly curtailed owing to a shortage of electric energy. These apprehensions have been allayed, so far as the near future is concerned, by the official announcement of the Northern Canada Power Co. that they have now sufficient water in storage to supply the Porcupine mines with power until the end of March. A big dam has been completed near the head of the Mattagami River, which will back up the water for about 30 miles, and raise the level about 10 ft. While an ample supply may thus be assured for present requirements, it is realized that the existing sources of supply are inadequate to meet the greatly increased demands resulting from the steady expansion of the gold-mining industry, and that the projects of leading companies for greatly increasing their output cannot be carried out unless more power can be secured. The question is now being closely considered by the power company and the mining interests concerned.

The Hollinger Consolidated during October treated 108,024 tons of ore, being an average of 3,858 tons per day. The management has planned the sinking of a six-compartment shaft to a depth of approximately three-quarters of a mile, considerably lower than has hitherto been attempted in connexion with Canadian gold mining. It is proposed to increase the capacity of the mill to about 6,000 tons of ore daily by a change in the grinding equipment, replacing the 200 stamps now used with ball mills. The company is now employing 1,970 men, and has upwards of 100 machines in operation underground.

A statement covering the operations of the Dome Mines for the six months ended September 30, shows a total income of $513,863. Deductions for taxes, depreciation of plant, and exhaustion of mine, totalling $369,712, leave a profit of $144,151. During September the tonnage handled was over 1,000 tons daily, yielding approximately $7 per ton. A large ore-body found on the 7th level yielding high-grade ore has been proved by diamond-drilling to extend downwards for at least 150 ft., but owing to its irregular shape its extent at depth is yet uncertain.

Work has been resumed at the Davidson with George E. Bent as manager. High-grade ore has been encountered in driving on the 600 ft. level. Diamond-drilling is in progress to prove the main ore-body at depth before proceeding with shaft-sinking and the erection of a mill. At the McIntyre some difficulties have been experienced in the treatment of the ore from the lower workings owing to the occurrence of carbon in the ore. Various experiments have been tried, and it is now believed that a process of oil flotation can be successfully adopted. The Premier-Paymaster is now in operation. The occurrence of a large ore-body has been proved, which has been opened up on the 200 ft. level. The shaft will be put down further. The Beaumont will explore the property at depth by diamond-drilling before attempting further extensive development.

KIRKLAND LAKE.—The output of the four producing mines of this camp amounts approximately to $5,000 daily, which is likely to be largely increased next year when additional mills will be working. The Lake Shore during September produced $40,928 from the treatment of 1,622 tons of ore, the average extraction being $25·23 per ton. A dividend of 2%, the third disbursement during the present year, has been declared. The Teck-Hughes is developing the rich ore-body occurring on its fourth level, the downward continuation of which has been established. Development work towards this body is being pushed on the lower levels. An electrically driven mining plant is being put in operation on the Sylvanite for sinking a new three-compartment shaft. At the Bidgood the main shaft is being put down to the 400 ft. level to open up at that depth the ore-bodies developed on the 300 ft. level. The Kirkland Lake mine is treating upwards of 4,000 tons per month, and development on the 900 ft. level has placed a quantity of high-grade ore in sight. The Granby-Kirkland is showing up well under development, 14 veins having been found, one of them about 6 ft. wide carrying good gold content. The shareholders of the Montreal-Kirkland have decided to resume operations and authorized the sale of 75,000 shares of treasury stock to raise the necessary funds.

LARDER LAKE.—The past few weeks have witnessed a great increase of activity in this district. Hundreds of claims, which had been abandoned after the boom of twelve years ago subsided, have been restaked, and prospectors are now eagerly searching any small areas which may have been overlooked. The Costello vein, a strong body of highly silicified basalt, varying from 15 to 60 ft. wide, which has a known length of 1 mile and is stated to carry gold in commercial quantities, extends over several properties, and is being opened up by the Canadian Associated Goldfields and the Crown Reserve. The Coniagas, of Cobalt, has entered the field, and taken over 300 acres on option.

COBALT.—The Nipissing during September mined ore of an estimated net value of \$197,536, and shipped bullion from Nipissing and custom ore of an estimated net value of \$164,405. The new vein found in August has been driven on, and a section of 60 ft., 3 in. wide, contains ore averaging 2,500 oz. to the ton. During the first nine months of the year the company produced approximately 2,022,000 oz. of silver, which is 15% less than the output of last year for a corresponding period. The decrease in value is about a million dollars.

The gross earnings of the Bailey custom mill in October were \$14,363 from the treatment of 4,787 tons of ore. The shaft of the Victory is being sunk from the 300 ft. level to a depth of 500 ft. A cobalt vein showing some silver, 2 to 5 ft. in width, has been encountered at the 185 ft. level, which is to be tapped at the 500 ft. level. The Right of Way Co. has been declared insolvent and is being wound up. The Peterson Lake has adopted a new scheme of financing by the issue of silver certificates bearing 10% interest and redeemable in two years. The company pledges its silver reserves as security for the payment of the certificates when due. It is hoped to raise \$100,000 in this way. The shaft on the Waldman property of the Oxford-Cobalt is down 70 ft., at which point the vein is reported to be strong, carrying considerable cobalt. The annual statement of the Hudson Bay for the year ended August 31 shows a loss of \$20,347. Work on the Chambers-Ferland mine has been suspended.

WEST SHINING TREE.—There has latterly been some renewal of activity in this area, which is attracting a good deal of attention as a field for investment. The Hollinger Consolidated, of Porcupine, has taken over thirteen claims on Granite Lake on option, and will make a test of the property by diamond drilling. A quartz vein 14 ft. wide runs across the group. An English syndicate has purchased outright the Kingston property, comprising 120 acres, at a price stated to be the largest ever paid for any property in the district. The Atlas will shortly be reopened and the shaft put down to a depth of 360 ft., the necessary funds having been secured by a sale of treasury stock. At the White Rock a vein has been stripped for 600 ft., and a shaft put down. On driving at the 65 ft. level the vein was found to have widened from 2 to 6 ft. and to carry ore averaging \$12 per ton.

VANCOUVER, B.C.

November 11.

THE BRITANNIA DISASTER.—Heavy rains throughout nearly the whole of the southern part of British Columbia between October 12 and 28 have done an immense amount of damage to property and have completely isolated the cities of Vancouver and Victoria from communication with Eastern Canada. In many places the rainfall for the 16 days was in excess of 10 inches, while on the 28th the fall in some places amounted to 3 inches. Disaster fell with a particularly heavy hand at Britannia Beach on the night of October 28, when at half-past nine part of the Britannia Mining & Smelting Company's water-impounding system collapsed, and a roaring torrent of water swept down the mountain and through the settlement, carrying houses, trees, and everything in its path into Howe Sound, and leaving a tangled mass of ruin in its wake. Men, women, and children to the number of not less than forty were either crushed by the falling timbers of their homes or carried into the Sound to be drowned. For several days before the catastrophe the company had kept a constant patrol on the banks of the creek, to see that everything was kept clear, but it appears that the continuous rains had caused landslides in the higher reaches of the creek, and these must have formed an immense dam at some point, which suddenly gave way, and the torrent of water brought down an enormous quantity of debris, breaking down some of the dams and forcing the water out of others. Both of the men that were patrolling the creek at the time were drowned, evidently in an effort to warn their fellow workmen and their families in the settlement below. The first rush of water put the electric-lighting plant out of

commission, and the darkness added to the confusion.

This is the third serious calamity that has befallen the Britannia Mining & Smelting Company and its employees within the last seven years. In the spring of 1915 an avalanche of snow and earth slid down the mountain side, demolished the boarding-house and eight other buildings, collapsed the aerial tramway, and killed 54 men who were in the boarding-house at the time. Last February fire destroyed the 2,500 ton mill, which was the largest mill and the first flotation plant to be erected in the Province.

On the day before the catastrophe Britannia Beach was rejoicing over the rescue of two miners, who had been trapped by a cave in the 3,100 level, and who had been rescued by the indomitable pluck and energy of their fellow workmen, after continuous hard work in relays for eight days, without taking time to support dangerous ground. The rescued miners, who had been without food all this time, were able to walk out of the mine, and, after a meal and a night's sleep, were little the worse for their harrowing experience.

Cariboo.—What promises to be an important new placer-gold discovery has been made recently at Cedar Creek, Quesnel Lake, in the Cariboo district. The original discoverers have cleaned up a considerable quantity of gold by rocking, and the whole creek has been staked in bench claims. Unfortunately the wet weather set in before the extent of the pay-streak could be determined, none but the original discoverers succeeding in reaching bedrock.

A. Sanders, who has been prospecting for the mother-lode of the Cariboo placers for the last three seasons, has made a promising discovery on Proserpine mountain, near Barkerville, consisting of a 30 ft. belt, which on the surface is composed of oxide of iron intercalated with numerous quartz veinlets. At fairly shallow depths the oxide turns into sulphide. The gold seems to be contained in the oxide, rather than the quartz. Assays of the oxide, which always gives a long tail on panning, have ranged between $380 and $450 per ton. It is likely, of course, that there has been a surface concentration, and it is improbable that these values will be found in the sulphide ore. A trial shipment is being taken out, but, with the present condition of the roads, it will be some time before it can be sent to the smelter.

Sheep Creek.—There has been a marked revival of gold mining in the Sheep Creek district, some 35 miles from Nelson. The Nugget Gold Mines, Ltd., which is operating the Nugget and Mother Lode groups, restarted early in the season, and, despite a stop of some six weeks on account of a shortage of water, has produced $60,000 worth of gold up to date this year. There are seven veins on the property, but only two, the Nugget and the Mother Lode, have been developed to any extent. These veins have been developed to a depth of 1,000 ft., and the company is about to start another tunnel, which will cut the veins at 1,500 feet. The mine is equipped with a ten-stamp mill, pebble mill, and cyanide plant. No gold is recovered by amalgamation. The plant is operated by water power obtained from Sheep Creek, which generally fails for a month or six weeks during the heart of the summer.

Oil Activities.—The California oil companies appear suddenly to have realized that, with the price of coal still ranging from $12 to $13 per ton in Victoria and Vancouver, and with the considerable shipping business that takes place from these ports, there is a big opportunity for the sale of oil. Recently the Union Oil Co. bonded the British Columbia Refineries property on Burrard Inlet, and purchased the old Kirkpatrick shingle mill, which is to be converted into a distributing station. In all probability a modern refinery will be built on the British Columbia Refineries' property. Directors of the Shell Oil Co. were in Victoria last week, negotiating for a site on the old Songhees Indian reserve, near the city. The Canadian Pacific company's new ocean liners, which are to be put into commission next year, are oil-burners, and those already in use are to be converted into oil-burners; the Canadian Pacific Railway's coastal boats also are being converted into oil-burners; add to this the industrial and domestic demand, which is ever growing, and it will be seen that it is likely that there will be a good market for oil in the coast cities of British Columbia.

The exploration for oil in the Canadian North-west has been disappointing. Nothing new has been found at Fort Norman, and the original discovery well has not yet been developed into a commercial producer. The Imperial Oil Company, undaunted by failure to date, is not only continuing the explorations in the province of Alberta, and in the North-west Territories, but has started geological reconnaissances in British Columbia,

and if these give promising results the ground will be tested by drills next year.

Probably one of the most favourable indications that the Imperial company has met up to now has been at Pouce Coupé. There the company has been sinking since the middle of the summer, and at a depth of some 1,800 ft. struck a strong flow of "wet" gas, estimated at about two million cubic feet per day. Drilling was stopped and the boiler was moved back, as it was feared that the fire might ignite the gas. After this had been done the drill was re-started, and had been in operation only 15 minutes when a still stronger flow of gas, estimated at eight million cubic feet per day, was struck. This gas is still blowing off as vigorously as when first struck, and it is so "wet" that it has the appearance of steam coming from the 21 in. bore. It is proposed to cap this gas, and use it as fuel for drilling a number of other holes. Pouce Coupé is situated far more conveniently as regards transport than many of the other places where the company has been exploring. It is on the Pouce Coupé River, a tributary of the Peace River, and is only about 75 miles from a branch line of the Canadian National railway system, and already a survey has been made to connect Pouce Coupé with that system.

A large number of oil claims have been staked near Terrace and Burns Lake, both on the Grand Trunk Pacific railway, and both places are to be tested by one or two drills next year. Companies have been organized and the drilling outfits purchased for this work. The Provincial Government has sunk two or three bores in the vicinity of Hudson's Hope, in the Peace River district, but has obtained no results.

PERSONAL

Clyde Allan left last month for Nigeria.

Ernest Bottoms has left for Nigeria.

George Bottoms is expected from Nigeria.

Vicars W. Boyle has returned to Nigeria.

Sir John Cadman has been appointed chief technical adviser to the Anglo-Persian Oil Company. He is now in the United States.

G. W. Campion is here from West Africa.

A. B. Climas has left for the Ervedosa tin mines, Portugal.

A. W. Cooke is back from Alaska.

W. H. Cusworth has been appointed works manager for Hadfields (Australia), Ltd., Sydney.

Dr. J. R. Falconer is returning to Nigeria next month.

R. J. Frecheville has moved his office from Salisbury House to 5, London Wall Buildings.

O. T. Gorton has returned to Portugal.

W. J. Humphreys has left for Prestea, West Africa.

H. F. Hutson is expected from Nigeria.

C. F. Jobling has left for West Africa.

S. J. Lett has left for Rhodesia and Zambesia.

W. J. Loring was elected for a second year as president of the American Mining Congress.

Ross Macartney is here from Rhodesia.

B. Hope Nicolson has left for Nigeria.

F. Douglas Osborne has been elected chairman of the Gopeng, Tekka, and other Malayan tin mining companies, in succession to the late James Wickett.

R. W. Palmer, of the Geological Survey of India, has been appointed lecturer in geology in the Manchester University.

W. Pellew-Harvey has returned from Australia by way of Canada.

J. H. Rich is returning to Tronoh.

William Russell, of the Dorr Co., is on a visit to South Africa, and is not expected to return before February.

R. R. Simpson has been appointed Chief Inspector of Mines in India.

Dr. L. Dudley Stamp has resigned as demonstrator in geology at King's College, London, and is leaving for Burma to undertake geological advisory work.

Dr. F. L. Stillwell has resigned as geologist to the Bendigo Amalgamated Goldfields, Ltd., and is now intending to visit South Africa, North America, and London.

Ralph S. G. Stokes has sailed for South Africa.

E. O. Teale is expected from Tanganyika Territory.

R. Arthur Thomas has been on a professional visit to Upper Silesia.

A. Beeby Thompson has gone to Burma for the Anglo-Burma Oil Company.

W. E. Thorne has returned from Nigeria, and has gone to California.

George H. Thurston is back from India.

E. R. Weidlein has been appointed director of the Mellon Institute of Industrial Research, Pittsburgh.

R. B. Wham has returned from Nigeria.

Alpheus F. Williams is here from South Africa and is going to the United States.

W. R. Wolton has left the Poderosa company, and has joined the staff of the Corocoro copper mines, Bolivia.

Arthur Blackman, a London solicitor, well-known for his excellent work in connexion with mining companies, died on December 3, after a long illness.

F. E. Armstrong, professor of mining in the University of Sheffield, died on October 28 at the early age of 42. He had extensive experience in coal-mining in this country, and also in Mexico and British Columbia. Not qualifying for war service, he volunteered for ambulance duty at the front, and remained in France for three years. Subsequently he returned to take control of the labour section of the Coal Mines Department of the Board of Trade.

E. Windsor Richards died on November 12 at the age of 90. In early days he was connected with the Tredegar Iron Works, and later became chief engineer at the Ebbw Vale Steel Works. From 1876 onwards he was general manager and subsequently chairman of directors of Bolckow,

Vaughan & Co., of Middlesbrough. His chief service to metallurgy was the development of the Gilchrist-Thomas basic bessemer process. He was a past-president of the Iron and Steel Institute and the Institution of Mechanical Engineers.

HENRY WILSON FOX died in London last month, aged 58. He was educated at Cambridge and was called to the bar by Lincoln's Inn. Subsequently he went to Johannesburg as a member of the staff of the Consolidated Gold Fields. He assisted John Hays Hammond in framing the Rhodesian mining laws, and among other and various activities he was editor of the *South African Mining Journal* and public prosecutor for Rhodesia. He returned to England in 1897 and was later appointed manager for the British South Africa Company, with which he had ever since been connected.

TRADE PARAGRAPHS

THE WESTINGHOUSE ELECTRIC INTERNATIONAL Co., of New York and London, send us their monthly magazine for December, and also circulars relating to the wide applications of electricity.

THE WESTINGHOUSE ELECTRIC & MANUFACTURING Co., of East Pittsburgh, U.S.A., send us their Christmas number of *Contact*, a paper giving the popular side of the firms' many manufactures.

VANADIUM, LTD., of 64, Victoria Street, Westminster, agents in this country for the Vanadium Corporation of America, have issued an illustrated booklet giving particulars of the corporation's mining and dressing plant in Peru.

BELLS' UNITED ASBESTOS CO., LTD., of Southwark Street, London, S.E. 1, send us their new catalogue relating to their Poilite sheets and tiles. Poilite is made of asbestos and portland cement, and is extensively used in building construction where freedom from fire risks is desirable.

BOVING & CO., LTD., of 56, Kingsway, London, W.C. 2, announce that they have a complete new set of lantern slides showing examples of modern water-turbines and hydro-electric installations suitable for lecture purposes. These slides are available for lending to institutes, technical schools, etc.

EDGAR ALLEN & CO., LTD., of the Imperial Steel Works, Sheffield, send us a copy of the *Edgar Allen News* for December. This contains articles on modern electric furnaces for heat treatment, and steel castings for cement-making machinery, and on certain points in connexion with the care and treatment of drill steels.

A double-acting two-stage air-compressor made by the ATLAS-DIESEL COMPANY, of Stockholm (London office: 35, Surrey Street, Strand), is described and illustrated in *Engineering* for November 11. This is said to be the largest air-compressor ever made in Sweden. It was built for one of the iron-mining companies in Swedish Lapland.

DANIEL ADAMSON & CO., LTD., of Dukinfield, near Manchester, send us their new catalogue entitled "Cheap Power for Every Need." This gives details of steam turbines, turbo-blowers, turbo-pumps, turbo-generator sets, condensing plant, Lancashire and Cornish boilers and boiler-house plant, piping installations, chimneys, boiler setting, and everything for traction, lighting, and industrial supply.

HOLMAN BROTHERS, LTD., of Camborne, have won a notable success with their "C.H.2" cradle hammer drill at the Van Ryn Deep. The results are believed to constitute a world's stoping record. The following are the details: Period, September 2 to October 1, 1921; number of machines, 3; working shifts, 26; machine shifts, 78; total fathoms broken, 248; fathoms per machine shift, 3·18; stope width 69 inches.

H. R. MARSDEN, LTD., of Leeds, were well represented at the Public Works, Roads, and Transport Exhibition held last month at the Agricultural Hall, Islington, specializing in their breakers intended for producing stone suitable for roads. Their Blake-Marsden "X" type is a breaker intended for heavy duty; its design is simple, the construction strong, the adjustment easy, and it is economical of power. The jaws are in two equal pairs, instantly reversible top to bottom respectively, thus ensuring maximum working life; the main bearings are away from the dust, the working parts are accurately machined, and the frame is strengthened by ribs extending round both sides and front. The Blake-Marsden "Y" type is an eccentric-motion machine, and is designed to combine strength, simplicity, and efficiency. The jaws are arranged as in the "X" type. The pitman has special arrangements for lubrication; the renewal of working parts is simple; and strengthening ribs extend all round the frame.

METAL MARKETS

COPPER.—The standard copper market in London was steady during November, such price movements as took place being comparatively small. Though sentiment became slightly more optimistic on the good American advices, little encouragement was offered by the aspect of the position in this country, where consuming demand continued unsatisfactory. As already indicated, the market here was dominated by the firmness in the United States, where the cent price of electrolytic rose from 13 cents to 13¾ cents during the month. The American revival is undoubtedly genuine; domestic demand has broadened substantially, and this, coupled with quite a good export business, is responsible for the appreciable increase recently recorded in sales. That sentiment has taken a decidedly good turn in America is shown by the fact that rumours have been current that some of the mines now closed might shortly reopen. It appears unlikely, however, that such mines will resume operations before the spring or summer of next year. Producers in the United States, meanwhile, have gained control of the market there, and values are likely to be steady, if not firm, in the near future. It might have been expected that values of standard would advance in sympathy with New York, but any possibility of a substantial rise here was scotched by the firmer tendency of the sterling exchange. An event of note during the month was the liquidation of the whole of the British Government stocks of copper, amounting to some 9,000 tons.

Average price of cash standard copper: November, 1921, £66 13s. 6d.; October, 1921; £67 8s. 1d.; November, 1920, £84 18s. 6d.; October, 1920, £93 10s. 1d.

TIN.—The tendency in the standard tin market in London during the past month was distinctly towards higher levels, and on balance values closed at a substantial advance. Various factors assisted

to bring about the better tone. It had been felt for some time past that the price of tin in London was decidedly low, and that whatever adverse elements the situation might contain were sufficiently discounted in the depressed quotation. With this state of opinion prevalent, the bad statistical position was practically ignored, while confidence was evident in an early establishment of something approaching equilibrium between supply and demand. This optimism was duly justified, for the statistics published at the beginning of December revealed an appreciable decrease in visible supplies during the month under review. Meanwhile, demand from British tinplate works continued fairly satisfactory, and towards the end of the month America came in as a buyer on a good scale despite the fact that the sterling exchange was moving unfavourably for the United States. This would indicate the extent of the present revival in the American tinplate trade. There was a fair Continental demand during the month. Sales in the Straits were on a good scale during the first two weeks or so, but later—as is so often the case when the London market looks like being in for a substantial rise—sellers there became more reserved. Batavia and China sold practically nothing during the month.

Average price of cash standard tin: November, 1921, £159 0s. 2d.; October, 1921, £156 10s. 4d.; November, 1920, £241 5s. 6d.; October, 1920, £258 8s. 8d.

LEAD.—The London lead market was consistently firm during the month. Holders appeared to have the situation well under control, and with arrivals of fresh metal restricted, values naturally had a hardening tendency. There was a diminution rather than an increase in the volume of English consuming demand, but a fairly keen inquiry from the Continent resulted at times in a very active business on 'Change. At the present time there is little doubt that Europe generally is suffering from a shortage of supplies, and Germany—herself a producer—is buying largely. There is very little Spanish metal arriving at British ports, the bulk of current shipments going to the Continent; and although some American lead has been coming in, the quantities involved have been insufficient to turn the scale. Prospects of any increase in arrivals in the near future are poor; for, although it is understood that metal is afloat from Australia, Burma, and Africa, the amount involved is not very large. There is little doubt that so far as the English consuming trades are concerned, lower prices are a necessity; and from this point of view every rise in the price is to be regretted.

Average price of soft pig lead: November, 1921, £24 4s. 10d.; October, 1921, £23 10s. 8d.; November, 1920, £32 5s. 6d.; October, 1920, £35 2s. 1d.

SPELTER.—Sentiment on the London spelter market was rather changeable during November. The tendency of values at the beginning of the month was somewhat easy, owing to fears of larger shipments from Silesia on the transfer of the spelter mines and works there from Germany to Poland, while, furthermore, the fact that arrivals during October were comparatively heavy was not without its influence. During the middle of the month, however, a steadier tone was evident, while, later, sentiment became more optimistic and values rose, a small advance on the month being registered. On the whole, the situation during the month under review experienced a little improvement. Demand from English galvanizers continued fairly satisfactory, and although there was perhaps no actual shortage of supplies, holders at no time displayed much eagerness to offer. As a matter of fact, stocks in the United Kingdom are still dwindling, which is a good indication of the present ratio of demand and supply. As has been the case for some time past, Continental producers offered very little, and it is fairly obvious that consumers there are absorbing the bulk of the output. It is worthy of note that the Belgian output is slowly broadening. Nothing materialized during the month from the scheme to resume operations at the English smelters, but it is possible that a restart may be made in the

near future. Meanwhile, the big Risdon plant in Australasia has commenced production. The market in America was firm during the first part of the month, but later on fell away somewhat. In view of the advance in sterling, this brings the possibility of American offerings to this country appreciably nearer.

Average price of spelter: November, 1921, £26 4s. 10d.; October, 1921, £26 10s. 7d.; November, 1920, £35 14s. 7d.; October, 1920, £40 5s. 6d.

ZINC DUST.—Prices are steady; Australian high-grade £50, American 92 to 94% £47 10s., and English 92 to 94% £45 per ton.

ANTIMONY.—Quotations are a little easier as follows: English regulus ordinary brands £34 to £37, special brands £35 5s. to £39, and 98 to 99% £25 to £28. Foreign material is quiet at £22 to £24 10s. for spot.

ARSENIC.—The price of Cornish white, 99%, is well maintained at £42 10s., delivered London. Foreign material is cheaper.

BISMUTH.—Holders continue to quote 7s. 6d. per lb.

CADMIUM.—Business is a little better at the unchanged price of 6s. per lb.

ALUMINIUM.—Home producers still ask £120 for home and £125 for export business; foreign metal can be had at £95 f.o.b. Continent.

NICKEL.—Domestic makers ask £185 for both home and export business; foreign material, however, is offering at about £175.

COBALT METAL.—The market is quiet, with the price at 14s. per lb.

COBALT OXIDE.—Values are unaltered at 10s. 9d. for black oxide and 12s. per lb. for grey.

PLATINUM AND PALLADIUM.—The market is steady; manufactured platinum £19 10s. per oz., raw £18; manufactured palladium £19 10s., raw £13 to £14.

QUICKSILVER.—Towards the end of November the leading interests advanced their price. The present quotation for second-hand material is about £10 7s. 6d. per bottle.

SELENIUM.—The price of powder is 9s. 6d. per lb.

TELLURIUM.—Sellers quote 70s. to 80s. per lb.

SULPHATE OF COPPER.—The price is easier at £27 to £28 for both home and export business.

MANGANESE ORE.—Business is quiet, the quotation being 1s. 2d. per unit c.i.f.

TUNGSTEN ORE.—A weak market at around 12s. c.i.f. for 65% WO_3.

MOLYBDENITE.—Values have weakened and sellers of 85% would now accept 30s. to 32s. 6d. c.i.f.

CHROME ORES.—Business is quiet and the quotation nominal at £4 to £4 5s. c.i.f.

SILVER.—The price of spot bars on November 1 was 40½d. Some support from China was seen, and the quotation rose to 40¼d. on the 2nd. Subsequently the price fluctuated within narrow limits, falling to 38¼d. on the 12th. A rise then took place, and on the 19th and 21st 39¼d. was quoted. By the 26th, however, the price was down again to 37⅝d., owing to absence of support. On the 30th the closing quotation was 37½d.

GRAPHITE.—Sellers now ask £20 to £23 c.i.f. for Madagascar 80 to 90%. Business is quiet.

IRON AND STEEL.—It was expected that further reductions in pig iron quotations would be delayed until next month, so that when it was announced at the end of November that pig iron would be cheaper, a certain amount of surprise was evident. No. 3 Cleveland G.M.B. is now £5 a ton, representing a fall from £11 5s. at the beginning of the year. Business, however, has been slow, and it remains to be seen whether buyers will be sufficiently attracted to place substantial orders. Hematite has been weak owing to the competition among makers to find buyers of their products as they are made, rather than have to put iron into stock. Italy has bought a little, while South Wales has also been a purchaser. East Coast mixed numbers are flat at 107s. 6d. to 110s. As regards finished material, a little more business has been coming in, but works are still only partly employed. Continental business is waning, owing to increasing difficulties in procuring supplies, except for far forward dates, from that side.

THE MINING DIGEST

A RECORD OF PROGRESS IN MINING, METALLURGY, AND GEOLOGY

In this section we give abstracts of important articles and papers appearing in technical journals and proceedings of societies, together with brief records of other articles and papers; also notices of new books and pamphlets, lists of patents on mining and metallurgical subjects, and abstracts of the yearly reports of mining companies.

THE MINERAL RESOURCES OF UGANDA

The first annual report of the Geological Department, Uganda Protectorate, covers the year ended March 31, 1920, and it is written by E. J. Wayland and W. C. Simmons, Chief and Assistant Geologist respectively. We give herewith some quotations relating to the general geology and the mineral occurrences. One part that we omit deals with the theory of the Rift Valley. It may be mentioned here that the Rift Valley was the subject of a paper by Mr. Wayland read before the Royal Geographical Society last month.

GEOLOGY.—The rocks of Uganda may be divided among eight age-groups. They are dealt with in the order of their comparative antiquity, which is as follows :—

(1) The Archæan Complex.
(2) The Argillite Series.
(3) The Post-Argillite Intrusives.
(4) The Older Lateritic Deposits and Associated Gravels.
(5) The Mount Elgon Series.
(6) The High-level Gravels and Recent Lateritic Deposits.
(7) The Mufumbiro Volcanics.
(8) Recent Deposits.

(1) The basement of Uganda, like that of Africa in general, is composed of a series of very ancient crystalline rocks, which are almost certainly Archæan in age. Among them a moderately fine grained biotite-gneiss, or gneissose-granite, is conspicuous ; but associated with it are many other types of granitic, foliated, and schistose rocks, most, if not all, of which may be paralleled in other parts of the continent. The biotite-gneiss frequently contains monazite and zircon, so that material for an age-determination by radio-active methods is not lacking. Quartz-schists and mica-schists are both present. In the former the ferro-magnesian constituent, which is always recessive, is represented by a white mica, commonly sericite, while both biotite and normal muscovite schists occur. Near Seconyoni, Archæan outcrops display some highly crumpled sericite-schists, which are probably the metamorphic equivalents of highly felspathic quartzose rocks. In some parts (north-east of Soroti, for example) every gradation can be traced between a biotite-schist and an augen gneiss on the one hand, and between the same augen rock and a porphyritic granite on the other. Rocks with well-developed augen structure are of local occurrence ; a fine example is to be seen near Moroto Post. It occurs in association with what may be provisionally regarded as a sheared pegmatite, and consists of greyish felspar phenocrysts, with indefinite boundaries, merging into a white granular felspathic matrix, which is divided by dark mica flakes into eye-shaped pieces varying in length from half an inch to several inches. The irises of many such "eyes" are represented by grey felspar phenocrysts. Imbedded in the more micaceous parts are reddish to mauve crystals of zircon, which may reach a quarter of an inch in length.

More or less hornblendic rocks are common in the Archæan group, as are hornblende-schists, and hornblende-epidote-schists. These are well developed in the Eastern Province, where actinolite and kyanite schists occur, as do sillimanite-bearing rocks, and dolomitic marbles. The granites and gneissose-granites sometimes contain (as at Soroti, for example) dark inclusions of an older basic rock, the composition of which has yet to be determined. Many of the porphyritic granites show a very remarkable parallelism of the phenocrysts, traceable over wide areas and coincident with the strike of the country.

While no order of sequence of the Archæan rocks is yet certainly known, there is some evidence for supposing the more schistose representatives to occur with the dolomites in the upper part.

Intruded into the Archæan complex is a pyroxene granite, bearing strong resemblance to the charnockite of South India and Ceylon. In general, it appears to be pre-argillite in age, but Mr. Simmons has recorded an instance where a pyroxene-bearing granite has apparently been intruded into a post-argillite fault ; the field relations of this occurrence, however, are not very distinct.

Gabbros and diorites occur in the Archæan group, and a highly quartzose frequently finely jointed and much crumpled rock is characteristic.

In many places pegmatites, which may be more or less normal or may be differentiated into highly quartzose and highly felspathic reefs, cut across or run parallel with the foliation of the gneisses and schists. The local abundance of pegmatites in the ancient crystalline complex, and their almost entire absence in the neighbouring argillites, suggests a pre-argillite age for these intrusives. A few instances of normal pegmatites cutting the argillites are known, but these may be correlated with a later granite.

The most extensive development of Archæan rocks in the country appears to be in the Northern and Eastern Provinces. They occur in many places in the Buganda and Western Provinces, faulted in among the argillites and coming to grass in blocks and ridges, particularly in connexion with the curious low-lying areas described under the name of "arenas." Traced in a westerly direction, through the Buganda and Western Provinces, the crystalline rocks become increasingly conspicuous and occupy successively higher altitudes, until Ruwenzori is reached, where they attain their maximum height in the continent of Africa.

(2) Resting unconformably upon the foliated beds of the Archæan is the Argillite Series, a thick series of clay-like rocks varying considerably in composition and colour. Although those strata among them that have suffered little from the more drastic

types of metamorphism vary considerably in appearance and hardness, gradations between extreme types are so common that there can be no doubt that the series is essentially one, and although they vary in composition from practically pure hydrated silicate of alumina to a highly siliceous deposit, the gradations are so fine that there is no alternative but to adopt a single name for the whole. Since clay is no longer a term of chemical significance, the name Argillite Series is tentatively proposed in recognition of the essentially clay-like or shale-like appearance of the majority of its members. The name is purely provisional, and has obvious disadvantages; it will be replaced by another when the age of the beds is known. It is probable that they will turn out to be of Karoo age. Red and brown are the more usual colours of the clay members of the Argillite Series, but grey, yellowish shades, banded white, blue, and black are among the variations recorded. The rocks are extremely fine grained and rather absorbent, a characteristic which is noticeable in the more siliceous varieties. They do not, as a rule, display jointing to any marked extent. Hollow cavities resembling the salt pseudomorphs of the British Trias are locally abundant.

Interbedded with the clay rocks are quartzites, conglomerates, and sandstones. The first of these frequently carry pyrites and pyrrhotite scattered through them; the second often resemble very closely the banket of the Rand; while the last recall some beds of the millstone grit of Britain.

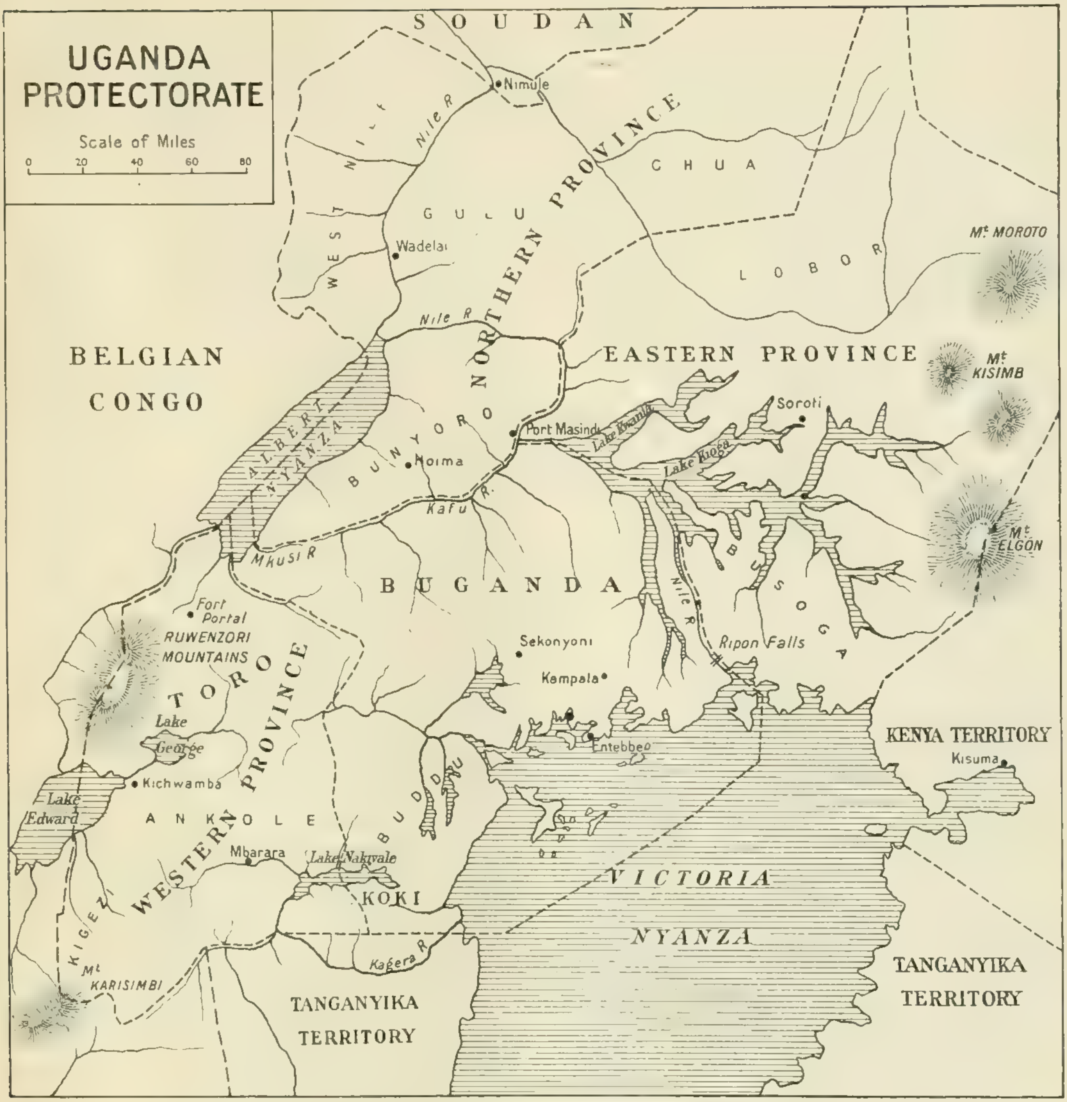
(3) The Post-Argillite intrusives may be broadly divided into acid and basic groups. Among the former quartz reefs are the most obvious, since they do not laterize and often stand out in bold relief from the red soil surrounding them. Frequently they carry iron ores which sometimes become very conspicuous; hematite is the commonest of these ores. It often happens that hematite is replaced by goethite at the surface. Quartz-tourmaline reefs, associated with highly tourmalinized argillites, are locally developed, while pegmatites and tourmaline-pegmatites, in which the tourmaline seems to take the place of mica, are known. Large granitic intrusions, probably laccolitic in form, make their presence felt in some areas; with them, probably, the smaller and more highly differentiated intrusives are genetically connected. The intrusions belonging to the basic group are chiefly of the nature of diabases, picrites, and pyroxenites. The basic intrusives generally give rise to a brilliant red soil, which appears to be extremely fertile. Not infrequently they can be traced for a mile or more in approximately straight lines. One of these picrite dykes holds back the Nile at the Ripon Falls, another at the Owen Falls near by.

(4) The Older Lateritic Deposits, which do not appear to be forming to-day, cap flat-topped hills which characterize Uganda and the adjoining country. They do not present any exceptional petrographical features, and may be matched in many other places in the tropics.

(5) With the exception of a basement of sedimentary (often conglomeratic) beds, which in all probability do not strictly belong to the series, the Mount Elgon Series consists entirely of volcanic rocks.

(6) As regards this division, high-level gravels and silts are very extensively developed in Uganda; they are associated with all the larger rivers and lakes, and are found at varying levels up to the 4,000 ft. contour in the case of the old lake deposits. They are to be found in small feeder valleys, where they may be more than 4,000 ft. above sea-level, as well as flanking large river valleys. In all instances investigated at present the main deposits have been shown to rest on old valley or lake bottoms above those of the present waters. The bottom gravels are flood-like in character, and the pebbles are often highly polished. Terracing occurs, two terraces being generally traceable. It is to be noted that the terraces are carved out of the gravel deposits by descending rivers; they are not cut out of the rocks. The fact that pot-holes are sometimes to be found on the ancient bottoms, which are overlapped by reason of the great horizontal spread of the alluvials above them, suggests that at one time the rivers rose considerably; in which case we should expect to find corroborative evidence in the lake depressions. The Albert Nyanza affords a good example; an old lake bottom (mud) well above the present level of the water and extending landwards to the base of the escarpment is overlain by extensive alluvial deposits which attain an altitude of more than 100 ft. above lake level; they are horizontally stratified, and are composed of a heterogeneous collection of boulders, stones, sand, and clay. The boulders, which are generally subangular, grow less common as the series is ascended. The horizontal stratification shows that the beds are not talus accumulations; while their constitution declares them to be of the nature of flood deposits.

(7) The Mufumbiro volcanoes rise from a plain well below the general level of the country to the east and north of it. The cones are well formed and large, the greatest (Karissimbi), situated within the boundaries of the Belgian Congo, reaches an altitude of 14,630 ft. They bear all the indications of recency, and one, Namlagira (? Namalagira), also in Congo territory, is still mildly active. As the necessary materials for the production of good petrographical sections are yet awaited little has been done in the matter of detailed rock determination, but it would appear from a few specimens examined that a good deal of the Kigezi lava is of the nature of olivine basalt. It is to be noted, too, that the olivine, which is sometimes present in individuals of ½ in. or more in length, is remarkably fresh, while the lavas and ashes themselves can be shown to have been spread over a landscape which is essentially that of the present day. They cover soils which must be comparatively recent. At the junction of the soils and the volcanic deposit, springs, the result of rain soakage through the latter, make their appearance. When the volcanic beds overlying such a soil happen to be ash beds they tend to slide over the surface of the soil, which is rendered slippery by the percolating water, and come gliding down to lower levels as land slips. Larger falls may be expected. Not all the craters in Kigezi are of the usual lava-emitting type. Many of them, especially those situated close to and among the surrounding argillite hills, are explosion craters blown through the rocks; they have emitted large quantities of ashes and bombs which now cover the country for miles around. Craters of this type probably represent an early phase in the volcanicity of the region. It would appear that these explosions were due to steam generated from water, which once occupied the depression in which the craters now stand. The eruption started, in fact, in the floor of a lake,



the remnants of which are still to be seen around the volcanoes. The lava cones were formed subsequently, probably immediately after the explosion phase. Many of the explosion craters were obliterated by the immense flows of lava which were subsequently poured out. No doubt many passed from explosion craters into lava craters; some, however, chiefly those in among and against the hills, were preserved by virtue of their screened position. There is evidence, too, to show that the main cones in the vicinity gave vent to three outpourings of lava, for they are still to be traced in horizontal sheets, whose edges form step-like terraces one above the other running east and west and facing northwards. Exactly when the major outpourings took place in the Kigezi district is uncertain, but the most conspicuous are, geologically speaking, very recent. Sections are not wanting which show that the present scenery and soil are continued beneath the ashes and lavas, and it can hardly be doubted that most, if not the whole, of the deposits have been spread over the area within human times. But it is possible that those situated further west are directly connected with the formation of the West Rift, with which the earliest outpourings might be contemporaneous.

Other volcanic rocks, some of which are moderately recent, are to be seen in the extreme west of Ankole and along the eastern side of Ruwenzori to some way beyond Fort Portal. Here, too, explosion craters are common, though small lava cones occur as well. At Kichwamba, on the eastern side of Kazinga Channel between Lakes George and Edward, the eruptions belong to two distinct periods; for the sub-aqueous tuffs by which the older volcanics are represented have been drilled through by explosions, a few of which have produced large circular

chimneys with vertical sides. A good many of these craters hold water, thereby giving rise to the famous crater lakes of the district; one of these contains water rich in soda and other salts. Near Fort Portal volcanic tuffs containing the impression of fossil leaves can be seen overlying ancient lake deposits, which are now high and dry above the neighbouring streams. Most of the tuffs contain a high percentage of calcium carbonate. It is probable that the older tuffs of Ankole, which form the western fault escarpment of the rift in this part, are connected, as may be those of Elgon, with earth-movements that preceded and eventually led up to the final phase in the formation of the African rift valleys. Provisionally, at any rate, the older Ankole tuffs may be correlated with the Mount Elgon lavas, while the newer tuffs and more recent cones of Ankole and of Toro may be grouped with the Kigezi volcanics. Whether the Congo volcanoes are situated within the rift depression or not, it is impossible to say, but there is no evidence to show that the high ground to the east of the Mufumbiro mountains in Uganda is separated from the low country from which the volcanoes rise by a fault; indeed, there is evidence to the contrary.

(8) The Recent Deposits consist of the usual clays, muds, sands, and gravels forming at the present day. They call for no special remark.

THE KAFU ALLUVIAL DEPOSITS.—Investigations were made of the geology of the Hoima district, Bunyoro, in order that some evidence might be obtained as to likely deep-lead deposits. The Kafu river is a big swamp system, and though it contains little water now, except when heavy rains have flooded the papyrus-choked swampy flats, and never any big flow, yet it is obvious from the size of the flat valley and the extent of the flood gravel deposits that it must, at one time, have been a big river. The present Kafu rises in a system of swamps, from which also the Nkussi river runs the opposite way into Lake Albert. It has been pointed out by the geologists that the Kafu must have risen at one time on the dome which has been let down by the rift faults to form the Lake Albert depression, and the River Nkussi has captured the head-waters of the Kafu and now flows back into the depression. The Kafu deposits have been found to contain small quantities of gold and more appreciable amounts of stream tin, so that these problems are not of purely academic interest, but become of the utmost importance in trying to locate richer deposits of these minerals.

The Kafu is now a papyrus-choked swamp, varying in width from a third to half a mile and more, and with a small water channel in the centre. The papyrus stands either in stagnant or feebly running water or in moist clay, according to the season or situation. At the sides are clay flats overgrown with rank grass and studded with acacia-thorn and other swamp-loving trees, and at the margins of this flat are slopes of gravel which spread out to the valley sides. The valley is of small slope and it is always difficult to draw a boundary between the laterite deposits of the sides and the true alluvials. Near the Kafu ridge on the Kampala-Hoima Road, the river deposits are about 2 miles wide, and this is about the average width, though they may extend to 3 miles or narrow to only a few hundred yards, as at the Mugabi ridge. The Kafu having been once a vigorous stream able to transport huge flood gravels and deposit them over its bed, it follows that the ancient gravels (or rather the gravels of the middle period, the most ancient being in terraces at the sides) might lie at the bottom of its valley under the later clay deposits, if its history since the loss of its watershed had been simply a dying off in the flow of water and a consequent "sudding up" of the channel. This is only partly the case, and though it has not been found possible to prospect the swamp near the river in the papyrus-belt by pits, owing to flooding, yet such evidence as is obtained points to the probability that the present stream deposits in the centre of the river are the lowest, though the ancient gravels are found to lie, under a thickness of clay up to 20 ft., at a level which is below the present stream bottom, but not necessarily below the present or recent erosion valley, which is now filled with mud. This is a point which will be easy of investigation when it is possible to put some small trial bores in the papyrus-belt. The rather hopeful results that are detailed here have been obtained from prospect pits only, on such sites as it was found possible to dig them.

The Chief Geologist, during his preliminary reconnaissance, had put two pits on the Singo side of the Kafu, one near the river and another a mile away on the gravel terrace, and he obtained a concentrate with small quantities of gold, which led to his pronouncing the gravels hopeful. The Assistant Geologist was therefore instructed to carry on with the prospecting of the gravels, and he started excavation on the Bunyoro as well as on the Singo side of the river, where the Kampala-Hoima road crosses it. The Bunyoro side is very different from the Buganda side at this place, for whereas on the Singo side the gravel flat is a mile wide, and the 3,600 contour lies 3 miles up from the stream, on the Bunyoro side the flat is narrow and the 3,600 contour is only a mile off. The first pit on the Bunyoro side bottomed on a white quartz reef at 9 ft. in the gravel of the terrace and yielded no gold, while on the Singo side the thin gravels just below the terrace yielded only minute traces of gold. It was then decided to dig a pit through the lay, nearer the stream on the Bunyoro side. This pit showed 15 ft. of stiff clay, which was most difficult to excavate, but at the bottom a gravel averaging 6 in. thick was struck, which rested on the decayed gneiss, a mixture of kaolinized felspar and quartz which had been found in all the other pits, and which at depth becomes harder and merges into more easily recognized gneiss. The bottom gravel here yielded fine gold and a few coarser grains, which gave distinct encouragement to continue prospecting. A pit was now put at the edge of the swamp on the Bunyoro side, and it was here found that after passing through 5 ft. of clay there was a sand bed of 9 ft. 6 in. thickness on the gravel bed, which was only 6 in. thick, and rested on a broken-down mica-schist in place of the gneiss. The gravel contained boulders of small size and yielded a much greater quantity of gold, though actual amounts were still far from approaching payable values. The gold occurs in little flattened grains, two or three of these grains of gold in every pan, and fine gold in appreciable amount. On the Singo side other pits failed to yield more than small traces of gold, so work was now confined to the Bunyoro side, and pits were put as near the present river-bed as the water would allow. The beginning

of the rains hindered the work at this stage and pit sites had to be chosen on the dryer places in the sides. Pit 11 was 350 ft. up stream from Pit 6, and it yielded concentrate in much greater amount from a gravel and boulder bed that was only 3 in. thick overlain by 3 ft. of clay on 11 ft. 6 in. of sands, which were easy to remove. This concentrate was sent to headquarters, and the Geologist was able to make a separation with the somewhat crude apparatus at his command, and found that this concentrate which was obtained from 6¼ cu. ft. of gravel, overlain by 370 cu. ft. of barren deposits, weighed 865 grammes, of which about 120 grammes (or 4½ oz.) were tin and the gold rather less than one grain. Among the gold was one larger grain than usual, about ⅛ in. long. It has been calculated from these figures that the values obtained for the pay dirt were about 1s. 6d. to the cubic yard for this pit, and it is to be noticed that the overburden here is quite barren but easy to remove. Other pits were put down near this site, and about the same amounts of concentrate obtained, but the best results were from Pit 15, which was 200 yards up stream from 11; here 18 in. of the gravel was overlain by 15 ft. of stiff grey clay, which was difficult to remove. The gravel was thicker and the yield of concentrate per yard considerably more, and gold about the same. Pits further up stream failed to yield any more concentrate or gold, as it seemed that the deep channel had swung away out from the Bunyoro shore. The ancient meanders of a sudded-up river whose channel is filled with clay deposits are difficult to follow, and to expedite the work simple boring apparatus would have much helped. Pit 16 was about 350 yards up from 15, and yielded a little less concentrate and about the same quantity of gold from a gravel bed 3 ft. 6 in. thick under 11 ft. of clay. Because it was found that the deep channel now swung away from the Bunyoro side a move was made up stream to Mugabi, where a ridge of quartz-gneiss strikes across the stream and the Kafu swamp narrows down to 250 yards across, though the ridge is also breached in another place north of the Kafu, and the river must once have used both gaps. The Mugabi site was chosen, partly because it was the only place accessible to the Kafu about there, and partly because it seemed that evidence would be there obtained as to whether the old valley was eroded deeply or not. The Mugabi ridge must have held up the river and caused a back-water, so that the usual gravels were not deposited there, or have been removed later. The lead was partially located well out in the swamp (as far out as a pit could be dug), and the usual concentrate with gold was obtained in small quantity in a coarse sand and boulder bed overlain by 16 ft. of moist clay. A line of pits was dug parallel to the Mugabi ridge, behind it, and extending from the Kafu to past the other gap, now occupied by only a small swamp. No further traces of gold, and only small patches of the gravels were located in these pits, thus proving that the lead lies out in the centre of the Kafu at this place. Rains had now begun to delay the work very much, and it was found advisable, for the want of boring apparatus, to leave the Kafu and take up the geological survey of part of Bunyoro.

The concentrates from the pits nearest to the swamp from the whole length of the river prospected are very uniform in character. They consist essentially of the following :—

Dark grains, black, brown, etc.: Ilmenite, magnetite, tin-stone, monazite, etc.
Pink grains: Garnet.
Bright red grains: Garnet, etc.
Green grains: Epidote and diopside.
Colourless grains: Zircons, apatite, quartz, etc.

The concentrate also yielded gold in coarse grains, of two types, flattened discoidal and much worn, and also more irregular shaped grains, with always very fine gold. On the average it seems to consist of about one-seventh part of its weight of tin-stone and to yield about two or three grains of gold to the cubic yard. So that the value of a cubic yard of the gravel is probably about 1s. 6d., but the thick, barren overburdens decrease this value very much.

The gravel consists almost wholly of quartzose rocks, either pure colourless quartz, or white, yellow, and brown quartz, and quartzites of various types, and differing much in the coarseness of grain. The pebbles are nearly all round or ellipsoidal and very much waterworn, so much so that the few fragments that are not waterworn can be soon sorted out. These angular ones vary in size from boulders a foot in diameter to minute fragments, and consist of the following: A hard, red, siliceous rock, resembling an impure jaspar, agate fragments, a few black siliceous rocks, fragments of quartz, and a few odds and ends. These angular fragments occur sparingly in the terrace gravels, but are more abundant, though never very abundant, in the gravel from the bottom of the valley. There they occur with boulders usually cuboidal in shape, and with partly rounded edges in some cases. Practically all the sources of these boulders have been located close above their place of occurrence. For instance, "greenstone" from an outcrop between the river and the road, gneiss of hard quartzose type from a ridge striking across the river 2 miles up from the road, quartzose boulders from the Mugabi ridge, etc. Also all the other subangular fragments (with the exception of the agate and jasper not located, but suspected to occur in the Argillite Series) can be ascribed to sources not far distant from the place in the river bed where they are found. The gravel always has a quantity of quartz in it, varying in size from the largest pebbles down to the minutest sand, and quite commonly the gravel has also a clayey matrix binding it into a hard mass; but in most of the pits yielding the best concentrates the clay is absent, and the bed is a brilliant yellow sandy gravel. Some of the pebbles in the bottom gravel bed are highly polished, and a few stone tools of human workmanship, also polished by Nature subsequently to the working, were found in the gravel in Pit 15. The polishing in not easy to explain, but it is best exhibited by hard siliceous yellow-ochreous pebbles from a rock probably belonging to the Argillite Series, and there are most of them to be found in pits where the floor is an altered mica schist. The occurrence of Palæolithic implements in the auriferous gravel in Pit 15 is interesting, and serves to prove that the bed was deposited either during or subsequent to the Palæolithic age. Very much more data are needed before the sequence of events in these river deposits can be unravelled, however.

(To be continued.)

GENESIS OF SPANISH PYRITES

At the meeting of the Institution of Mining and Metallurgy, held on November 17, H. F. Collins presented a paper entitled: "The Igneous Rocks of the Province of Huelva and the Genesis of the Pyritic Ore-bodies." We give herewith the summary, followed by extracts from the paper relating to the author's suggestions as to methods of enrichment. Firstly the summary:—

The igneous rocks of the province comprise contemporaneous lava-flows, tuffs, and ashbeds, as well as the granites, diorites, diabases, and porphyries described by previous writers. They all show a certain similarity marking them out as belonging to a definite petrographical province, particularly in regard to the universally low proportion of alkalis and high proportion of iron, and to the general occurrence of oligoclase and augite as the predominant felspathic and ferro-magnesian constituents respectively, the latter being in great part altered to chlorite.

All the rocks contain notable quantities of copper, zinc, and pyrites as accessory constituents.

The diabases and porphyries are most closely related to the ore-bodies; they appear to belong to the same general period, antedating that of the latter, and to exhibit almost every gradation in composition between a basic olivine-dolerite and a siliceous trachyte-porphyry.

As to the relative ages of the igneous rocks, it is easy to dogmatize but thoroughly unsafe to do so in the absence of more detailed study and definite information. The author was formerly inclined to consider the granite as the earliest in point of time of the intrusions, and the diabase as the latest, but only from analogy and on general grounds, since evidence is lacking to justify any positive pronouncement on the subject.

The pyritic ore-bodies have been formed by gradual replacement along shear-zones, mostly at or very close to contacts between the tilted sedimentary rocks and the porphyries and diabases. The sheared rock replaced is in most cases slate, but sometimes porphyry. The solutions that effected the mineralization doubtless had their origin in the underlying magma, from which all the igneous rocks now visible at surface were derived by differentiation.

The pyrites formed by the primary replacement was, beyond the influence of superficial secondary (chalcocite and covellite) enrichment, almost invariably poor in copper (2% and under, generally under 1%).

As the circulation of mineralizing solutions became less violent, owing to cooling and to the local cessation of earth movement, the solutions became relatively more highly charged with copper than with iron, and produced local primary impregnation in the pyrites already deposited, which may be called "deep-seated primary enrichment."

A further enrichment with chalcopyrite has been in many cases effected through the infiltration of solutions laterally from the dykes of diabase and porphyry which so frequently run parallel to the lodes and at a short distance from them; this may be termed "lateral primary enrichment."

We proceed to quote the author in detail as to the enrichments mentioned in the preceding two paragraphs.

The occurrence and extent of what is ordinarily known as secondary enrichment in these pyrites, lodes, and masses, due to the percolation downward of solutions containing copper sulphate derived from the leaching out of the gossan zone, or of the portion of the lode removed by denudation, and the precipitation of the copper (chiefly as chalcocite) upon the underlying unaltered pyrites, are already sufficiently well known. The extent to which the enrichment has progressed downward depends partly upon the depth of ore leached or denuded away, and partly upon the height of the outcrop above the local drainage level of the near-by ravines. It is too often assumed, however, that all local enrichments of the ore-bodies owe their origin to this cause, and that the course of the enriching solutions has been invariably downwards. The author distinguishes in these ore-bodies two other kinds of enrichment which, although both posterior in their occurrence to the formation of the masses, may yet be called "primary" to distinguish them from that resulting from the purely "surface" agencies referred to. These he refers to as "deep-seated" and "lateral" primary enrichment respectively.

In the first-named type the primary chalcopyrite may take the form of myriads of interlacing strings and small patches distributed over a considerable area of the cupreous pyrites, or it may form bunches many pounds in weight of nearly pure chalcopyrite. The author believes that this first type owes its origin to the gradual dying out of energy and falling off of the iron and sulphur contents in the mineralizing solutions, accompanied with a lowering of temperature due to cooling, coupled probably with a lowering of pressure, the result of contraction and possibly also of denudation. The first solutions were most highly charged with iron and sulphur, and the first process of mineralization was to produce enormous quantities of the pyritous slates (with all proportions of pyrites from 20% up to 80%), which are found everywhere throughout the district, and which are known as "azufrones"; these are invariably poor in copper. They are frequently found on the margins of lodes, but frequently alone in large masses unaccompanied by workable ore-bodies. This first stage of mineralization was probably rapid, and brought about by the circulation of large volumes of solution highly charged with sulphur and iron. As cooling proceeded in the intruded and underlying magmas the solutions carried a less proportion of iron and sulphur, and became more highly charged relatively with copper, thus depositing concurrently the intimate mixture of pyrites with chalcopyrite which is known throughout the world as cupreous pyrites. The richness in copper of this primary ore very likely depended largely upon the rapidity of its deposition, for even if the solutions everywhere carried about the same amount of copper (a surmise which would appear to derive some support from the relatively uniform copper contents of all the eruptives in this petrographical province), a higher grade of cupreous pyrites might be deposited from solutions carrying less iron and sulphur or circulating less rapidly and vice versa.

An interesting fact in connexion with this type of "deep-seated primary" enrichment is that with the chalcopyrite is frequently associated blende

and galena in notable quantities, as well as more rarely tetrahedrite and bournonite. The two former minerals occasionally predominate over the pyrites, makin a complex banded ore, which when rich in copper and comparatively low in lead and zinc, is often smelted for its copper contents, but when high in zinc and lead is sold for shipment to works that make a specialty of extracting these metals. When neither the copper nor the zinc is high enough, these ores are sorted out from the copper ores and form a waste product of the mining operations.

The other type of "primary" enrichment to which attention should be drawn is of a very different nature, and lends itself to much interesting speculation in regard to the channels taken by the mineralizing solutions. Thirty or more years ago a Spanish engineer first drew attention to the fact that in a considerable number of cases the ore appeared to be richer in that part of a pyrites mass which was nearest to the dykes of porphyry or diabase that so frequently run parallel with the lodes. The author has examined many of the ore-bodies, with special attention to any shoots of ore that might be noticeable and to their possible origin. Shoots distributed longitudinally are not very common, and they appear to be always explainable on the theory of reopening and later mineralization. Apart from these, however, there are many examples of transverse shoots, and these appear to be generally associated with transverse joints running from wall to wall, somewhat obliquely. Such transverse joints are sometimes very frequent, and they are very often filled with a mixture of chalcopyrite, quartz, and other minerals.

The author gives a number of instances, of which those at the San Platon mine are from the point of view of lateral enrichment more interesting than almost any others in the province. There are at least four principal ore lenses, overlapping both in dip and strike, and they occur wholly in the slate formation, a large dyke of porphyry showing, however, on the hanging-wall, north side, at about, 100 yards distance. In the old mine, worked by open-cut, only one lode was known (the southernmost), the other two being "blind." At the capping of these two lodes they are very narrow and consist of cupreous schists and complex zincy ore with some chalcopyrite, but soon widen and yield rich cupreous pyrites. The extreme northernmost lode or lens, for instance, where first discovered by cross-cutting on the fifth floor, was little more than a joint, as on the fourth floor; on the sixth floor, however, it widened out to 1 m. to 5 m., yielding ore of 4% to 8% copper. The main or south lode yielded rich ore (4% to 6%) at surface from the opencut, being secondarily enriched with chalcocite, but at the fifth floor this ore contains only 0·8% copper, and at the sixth only 0·30%. At the fourth floor on the south or foot-wall side it contains 0·8% to 1% copper; on the north or hanging-wall side 1¾% to 2%. All the lodes show many transverse joints from wall to wall, nearly at right angles, but there is little sign of motion in these and practically no joint filling; the transverse joints, however, mark off transverse blocks in the ore-body, each of which is either richer or poorer than the adjoining block, that is, there appears to have been impregnation by chalcopyrite subsequent to formation, and limited in a sense longitudinally to the ore-body by the cross-joints. Like the south lode, the other two show more chalcopyrite impregnation on the north or hanging-wall than on the south or foot-wall, the average difference being about 1%, for instance, 2½% copper on the hanging side, and 1½% on the foot-wall. A still more interesting feature is that the west end of each lens is always rich and the east end invariably poor Upon closer examination it appears that it is always the part of each lens which is overlapped by the next that is rich. Taking, for instance, the second or so-called north lode, this is rich throughout on the fifth floor (the north lode being always 1% richer on the average than the foot-wall side) and does not much fall off in grade on the sixth floor until the northernmost or new lode comes in to overlap it at its eastern end. Similarly with the other lenses, as each becomes overlapped on its strike and dip by the next successive lens (the general axis of all the lenses being on a line pitching steeply to the NNE.), it becomes impoverished in copper, or rather it is only the part of each lens not so overlapped that has become enriched. The foregoing facts can only be explained upon the assumption that there has been a chalcopyrite enrichment which has come in laterally from the north side of all the ore-bodies alike, that is from the porphyry dyke, which is a very prominent feature in the landscape about a hundred yards to the north of the ore-bodies. Since the enrichment is of chalcopyrite and not of chalcocite, it must be considered as primary in the sense of not being due to the superficial agencies that have caused the ordinary secondary enrichment.

In connexion with this lateral secretion theory, it may be mentioned that the author has shown that the whole of the rocks of the mineral belt of the province of Huelva, whatever their origin and composition, and whether comparatively near to ore-bodies or remote (in some cases at a distance of many miles), contain both copper and pyrites. It is noteworthy also that it is by no means those rocks which are nearest to the ore-bodies that contain the highest proportion of these ore-forming constituents; in several instances, indeed, the contrary would appear to be the case.

CORBOULD'S COPPER EXTRACTION PROCESS

The *Proceedings* of the Australasian Institute of Mining and Metallurgy No. 42, 1921, contains a paper by Percy Burbidge describing the process for leaching low-grade copper sulphide ores, worked out by W. H. Corbould, manager of the Mount Elliott mine, Queensland. This process was mentioned in the Mount Elliott company's last yearly report, to which reference was made in the MAGAZINE for January of this year, and it is believed that it will be applicable to the large reserves of low-grade ore available at that company's mines.

The essentials of the process are as follows :—

(1) Fine grinding followed by a sulphatizing roast.

(2) Agitation with acid solution produced within the process by electrolysis.

(3) Purification of a portion of the mother liquor and electrolytic deposition of the contained copper,

thereby producing sufficient free sulphuric acid in solution for the next charge of calcine and further requirements.

(4) Partial purification of the remaining mother liquor, together with the first wash solutions and precipitation of the copper content as hydrate by milk of lime.

(5) Dissolution of the copper in the hydrate precipitate by means of a solution of ammonia, followed by distillation of the ammonia liquor, producing pure copper oxide, and recovering the ammonia by condensation.

(6) Reduction of copper oxide to metallic copper.

(7) Treatment of the residue from (5) for the production of a by-product and the recovery of any remaining copper.

(8) Treatment of the washed slime residues from the ore charge for gold and silver by the cyanide process.

(9) Use of producer gas for the whole of the metallurgical operation as heating gas and to provide sulphate of ammonia.

The dried ore is crushed to 1 in. size, and then ground to 30 mesh.

As regards roasting, the essential requirements, temperature control and large capacity, demand a radical departure from existing types, and to obtain them the furnace shown in Fig. 1 was evolved. In the operation of this furnace the ore charge is subjected to heat by radiation and conduction through the internal tube system, and at the same time to alternate pressure and exhaust through the filter-boxes. The Corliss-type gear is so arranged that a rapid change from pressure to exhaust or change of ratio of duration of pressure and exhaust can be effected by means of the adjustable duplicate cams. This arrangement has great advantages in heating up the charge to the reaction temperature (about 560° C.) without the danger of over-roasting, and allows the charge to be maintained at the correct temperature during the time necessary to complete the catalytic action. During the first stage of the roasting the valves may be set to produce a gas rich in sulphur dioxide, which will be compressed and stored for use in a later stage. When sufficient gas has been thus obtained, the cams may be quickly adjusted while the furnace is in motion to introduce more air.

The furnace is heated by gas as shown, and the products of combustion pass forward and back along the internal tubes, thence by further pipes along the wall of the furnace and finally to the stack. This arrangement allows of a high temperature at the point of combustion without overheating the ore bed. The air delivered to the ore charge is pre-heated by passing through the stack, thus further utilizing the waste heat of the combustion gases. In operation, the furnace is charged about half-full and revolved at a speed of a quarter to half a revolution per minute. The completion of the roast is ascertained by withdrawing samples of the charge from conveniently arranged plugs, and making a simple test of the amount of water-soluble copper. The finished charge is released by turning down the furnace over the tunnel provided with a flight conveyor and opening the discharge gates.

The hot calcine passes to the cone mixer, to which is simultaneously added sufficient sulphuric acid solution to form a 1 to 1 pulp for the dissolving

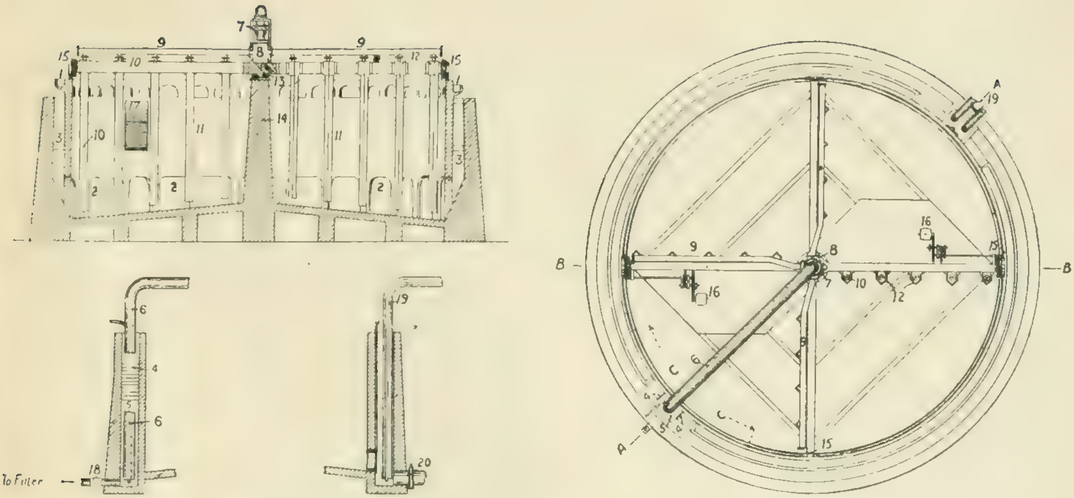

FIG. 2. -DISSOLVING AND WASHING PLANTS FOR CORBOULD'S PROCESS.

tanks. For an ore containing 5% copper, the stock solution made up from by-passed electrolyte will contain about 3·5% free H_2SO_4 (100%) and about 1% Cu. Fig. 2 shows the dissolving tank. The tank is charged through the launder (1) arranged to distribute pulp evenly round the tank. Light slimy liquors or wash waters flow under arches (2) through sand into the annular compartment (3) and over adjustable sills (4) into circulating box compartment (5), and are forced up by an air lift (6) through the acid-proof stuffing box (7) and four-way piece (8), thence along pipes (9) to vertical pipes (10) in wooden vertical agitating arms (11), and from thence the cycle is repeated. Agitating arms (11) are held in cast-steel sockets (12) fastened to the revolving girder-frame, supported in the centre on ball-bearings (13) mounted on the central pillar (14). The outer periphery of the revolving frame is supported on wheels (15) running on a circular rail round the top of the tank. Two wheels are geared to electric motors (16). After the driving motors have been stopped, mother liquor or various slimy wash solutions flow to box compartment (5) for slimes from annular compartments (3) to be sent back to the dissolving tank. Air is then shut off, and the liquor in the tank allowed to settle, which settled liquor is now drawn off over two central adjustable sills (17) into the annular compartments (3) to flow into box compartments (5) thence through cock (18) to filter to clarify liquor. In discharging, air lifts (19) are in duplicate. The pulp from the air lifts goes to a cone settler to denude it of coarse sand. The overflow from the settler goes to a Dorr thickener. The overflow from the thickener gravitates back to the dissolving tank to provide water to complete the emptying of the tank. The last water in the tank is discharged through the sluice-valve (20).

Air, preheated by waste heat from furnaces or gas coolers, is used in the air lifts. Copper sulphate and oxide being much more soluble in hot solutions than in cold, the utilization of heat in this way causes a great reduction in the time of contact necessary. All wash solutions go to separate tanks, the second wash solution becoming the first wash for the following charge, and so on, with the exception of the solution required for the gas plant. Clean water is used for the final wash, and owing to the use of milk of lime precipitating the copper from solution, a most efficient washing of the residues may be conducted, which in other methods would be impossible on account of the accumulation of a large tonnage of solution too low in copper to be utilized profitably.

The quantity of mother liquor taken for separate treatment is calculated so that the amount of copper contained will provide by electrolysis only sufficient free H_2SO_4 for the following purposes :—

(*a*) To dissolve the acid-soluble copper in the ore charge.

(*b*) To react with all the acid-consuming minerals such as the carbonates of lime and magnesia which remain unaltered after a sulphatizing roast.

(*c*) To acidulate the following mother liquor after neutralizing the purifying, before sending it to the electrolytic tanks.

(*d*) To dissolve the small percentage of copper and iron remaining in the $CaSO_4$ residue from the ammonia treatment.

The liquor, as calculated for the above requirements, is run to a special cone-bottomed vat and subjected to thorough oxidation by compressed air. Very finely divided (slimed) carbonate of lime is gradually added, only sufficient in total quantity to neutralize the free H_2SO_4 and precipitate the greater proportion of the iron or other impurities. The precipitate is filtered off and washed in an acid filter press, the filtrate being returned to the same vat and the washings sent to the main wash-solution storage-vats. The residue is treated later and marketed as a fertilizer.

Agitation is recommenced in the same vat, the temperature maintained, and according to the iron remaining in solution, a calculated amount of pure CuO from the ammonia process is added, precipitating the iron after the well-known reaction of Hofman. The residue is filtered off and washed as before, but in this case it is returned to the furnace bins for roasting with the next ore-charge, the iron of the residue remaining insoluble and the copper being recovered in the dissolving tank.

The purified solution of $CuSO_4$ is now acidulated by means of by-passed electrolyte to the extent of 1% free H_2SO_4 and is sent to the electrolytic

tank house. Electrolysis is conducted with a current of 12 amperes per sq. ft. of cathode surface, the anodes being of graphite and with arrangements for introducing SO_2 gas under pressure into the electrolyte for depolarization. In the presence of SO_2 the electrolysis of $CuSO_4$ solution results in the production of 2·3 lb. of free H_2SO_4 per lb. of copper deposited. Using this factor (2·3), the amount of free acid to be produced is calculated in advance, all electrolyte being by-passed from the tank house with a copper content of 2%. On account of the iron in the electrolyte being maintained below 0·2% (20 gm. per litre), it is possible to use graphite anodes yielding about 3 lb. of copper per kw. hour with a current density of 12 amperes per sq. ft. Current efficiency is thus kept high, a most important consideration where power is expensive.

The first wash solutions, together with the remaining portion of the mother liquor, go to a similar cone vat where they are given the same treatment with air and carbonate of lime for neutralization and partial precipitation of the iron or impurities. After the residue is filtered out and washed as before, the warm solution is agitated with gradual additions of milk of lime to produce as near as possible a selective action, that is, to precipitate most of the remaining iron with very little copper. The precipitate from this treatment is filtered off, the filtrate returned to the vat and the residue sent to the furnace bins with the next ore-charge. Further milk of lime is added, until all the copper is precipitated as hydrate, which readily settles and filters in a warm solution. On filtering the clear solution is utilized to make up the stock solution for the following roasted ore-charge by diluting the calculated quantity of acid electrolyte by-passed from the tank house.

The filtered residue, a concentrate of all the copper of the above solutions in the form of hydrate together with $CaSO_4$ and a little iron is immediately transferred to a sealed agitation vat and agitated with a solution of ammonia. The ammonia solution of a strength slightly in excess of two parts of NH_3 (100%) to one part of copper by weight, rapidly dissolves the copper hydrate, and on completion of the dissolution, the pulp is forced through a filter-press, the filtrate passing to a steam-jacketed still. The first washings of weaker ammonia solution are also passed to the still, and subsequent ores are stored for use on the next charge. All these operations are conducted in an ammonia-tight system, the storage vats for the weaker washings being arranged so as to be hermetically sealed. The treatment in the still consists simply in forcing steam into the copper-ammonia solution and condensing the ammonia driven off, the still being heated by steam in the jacket. The distillate is stored in steel tanks for the following charge. When complete elimination of the ammonia is effected, the steam is shut off, the precipitate allowed to settle and the clear solution decanted through a filter to the coolers at the gas plant, where the $CaSO_4$ in solution is concentrated. On the solution becoming saturated the $CaSO_4$ drops out, is recovered, and converted to pure plaster of Paris. Any ammonium sulphate in solution is similarly recovered.

The settled precipitate of CuO is washed by decantation and the amount required for the purification of the mother liquor for electrolyte is withdrawn to storage. The remainder of the CuO is conveyed to a small revolving furnace similar to the roasting furnace, where it is heated in an atmosphere of water gas. The reduced material is conveyed to a melting furnace where the metal is fused, poled, and cast into ingots as best selected copper. This method of reduction obviates the production of a quantity of high-grade copper slag.

The washed residue from the ammonia treatment is discharged to a mixer and sufficient by-passed electrolyte is added to dissolve the contained iron and copper hydrates and convert the little ammonia still remaining into sulphate. The pulp is filtered and the residue of $CaSO_4$ is washed and treated with previous $CaSO_4$ residues for the manufacture of fertilizer. The filtrate and washes are treated selectively with milk of lime to eliminate iron. The precipitate resulting is returned to the furnace with the next ore-charge. A portion of the solution is now passed through the ammonia absorbers of the producer gas plant. The NH_3 of the water gas combines with the $CuSO_4$ in solution, producing the characteristic azure-blue colour. On transferring this blue solution back to the remaining portion of treated solution, the copper in both portions is immediately thrown down as hydrate, which is filtered off, dried, and conveyed to the reducing furnace to be converted to metal by water-gas. The filtrate is now concentrated to recover ammonium sulphate, a portion of which product is heated with lime to obtain ammonia. Purified weak wash solutions from the dissolving tank are given a similar treatment to the above when required to absorb the balance of NH_3 produced from the coal. Any excess of ammonium sulphate above that required to make up the waste of ammonia in the process is disposed of as fertilizer with the $CaSO_4$.

In most cases the precious metals in the ore are combined with the copper minerals, and after the extraction of the copper, the gold and silver concentrate in the slime. On agitating this slime with cyanide the precious metals are extracted together with some copper, of which there remains about 0·3% in the tailing.

To start up operations a special charge is roasted and the water-soluble copper extracted. After purifying the liquor obtained, a small quantity of purchased acid is required for the necessary acidulation and the subsequent electrolysis will provide free acid for the future operation of the plant. The ammonia required will have to be procured until the producer gas plant is in operation, after which the losses to be made up will be no more than in good freezing plant practice. Water consumption will be the amount of moisture discharged with the residues, the amount evaporated, and the waste steam of the power plant not condensed, including that required in the producer plant. Solutions after treatment with milk of lime are perfectly free of copper. The $CaSO_4$ formed in the hot solutions causes no trouble in pipe lines. Throughout the process all solids filter readily. Reagents are regenerated or converted to by-products. There are no foul solutions, no solutions are discarded, and no copper is tied up in unfinished products. The process is a chemical one, and each step may be calculated chemically. If excess $CaCO_3$ be used to purify solutions, the excess will be coated with an oxide of copper. Coarse $CaCO_3$ has little or no action in purifying. Milk of lime should be as free as possible of $CaCO_3$. Solutions of $CuSO_4$ should be warm, not boiling, when under

treatment. Milk of lime should be gradually added, otherwise precipitation is impeded and excess of lime precipitate is accumulated. Copper hydrate precipitate should not be kept too long before treatment. Ammonia solution for dissolving should be about 20% NH_3 and only the final wash for the residue from the ammonia treatment should be clean water. Previous washes should all be weak ammonia solutions, otherwise Cu is precipitated out of solution. As power is expensive at most mines, it is much cheaper to produce electrolytic copper from a portion only of the liquors as required to produce the necessary H_2SO_4, and to convert the excess copper in solution to oxide, thence to metal, than to electrolyse the whole of the solutions from the ore charge.

Petrol from Natural Gas.—In his paper, read before the Institution of Petroleum Technologists on November 8, A. Beeby Thompson reviewed the question of prevention of waste in oilfields, and mentioned a great variety of ways in which waste may be eliminated. One of his points, well known to American oil-men, but usually neglected elsewhere, was that petrol or gasoline can be recovered from the gas coming from the oil-wells. We quote herewith Mr. Beeby Thompson's reminder on this subject :—

There are few oilfields which do not yield gases containing hydrocarbons that can be recovered by absorption or condensed to a liquid form by compression, refrigeration, or both. During the early career of oilfields the gaseous products may be very largely methane, but there is usually also a portion of the higher homologues of the paraffin series, and their proportion increases with the development of the field. The largest amount of condensable hydrocarbons are present where a partial vacuum is applied to the wells, that is, when a field is approaching exhaustion. Subjected to pressure or refrigeration, or both, hydrocarbons whose boiling points fall below the temperatures and pressures applied are liquified, and on exposure to atmospheric conditions they do not entirely revert to the gaseous form. Generally on liberation from the high-pressure condenser they boil, and the losses may be considerable, but if the lighter fractions are allowed to escape slowly without too violent agitation of the mass a varying quantity of a fairly stable product remains. The weathering of gasoline products extracted by pressure is, however, a wasteful procedure, as with some gases the greater part may spontaneously volatilize, leaving but a small fraction of that produced. It is by blending with heavier refinery distillates that the condensates of gas plants can most economically be retained and marketed. Mixed in suitable proportions with heavier gasolines they will lighten the gravity and not raise the vapour tension of the whole beyond that dictated by caution or permitted by law. The rising price of gasoline in the United States has caused those casing-head gases rich in gasoline to become a valuable and most sought for commodity, and high prices have been paid for installations that had secured gas rights over large areas at low rates.

The usual compression plants consist of compound compressor units of 200,000 to 5,000,000 cubic feet per day at 150 to 300 lb. pressure, either direct or belt driven from gas engines using some of the treated gas. The compressed product is passed through a water-cooled condenser from which the condensate is automatically trapped, while the escaping dry gas, after being expanded in a chamber forming the last section of the cooler, is led away for fuel requirements. Only careful consideration of each individual case will make it possible to say what gasoline contents can be made payable in any particular area, as it depends upon the cost of collection or purchase of gas, facilities for blending and transporting the desired products, the cost of installing the plant, and the uses for residual gas. Rarely can compressor plants be profitably operated with gas containing less than one gallon of gasoline per 1,000 cubic feet.

Some gases containing sulphur products cause such rapid corrosion of the valves and cylinders that the use of compressors is impossible, and at other times large percentages of carbon dioxide or nitrogen or of air, in the case of air propulsion, may render compression unprofitable even if the gas contains heavy hydrocarbon vapours. Such factors as the foregoing, together with the impossibility of profitably treating low-grade gases, led to the introduction of absorption processes which are now displacing the compression and refrigeration types. Most absorption processes rely upon the absorptive properties of certain petroleum distillates for lighter hydrocarbons, which later can be expelled by heating, and the recovered absorbent after cooling used over and over again ; indeed, a continuous cycle can be maintained of absorbing, expelling, and returning the chilled absorbent.

By means of absorption, gases can be profitably treated under favourable circumstances with contents as low as 1 pint per 1,000 cubic feet. Inflowing gas under as high a pressure as possible is allowed to meet a descending flow of suitable absorbent in vertical towers where convenient baffling is interposed to ensure intimate contact of the two fluids. The liquid from the towers is conducted to a still, where, during passage through a series of chambers, its light contents are expelled by heat, and the freed absorbent is returned to the towers, being subjected to cooling in its progress. By counter-flow arrangements the outflowing hot liquid is made to heat up the inflowing absorbent. Even with this process the gasoline is often wild, and unless somewhat intricate complications are included that provide for the condensation and return to the circuit of products evolved on release of pressure much light-density petrol is lost. The process does, however, appear to yield a more stable product than compression, and varying methods of absorption undoubtedly influence the quality of the product.

One step further has now been reached by the discoveries of Messrs. Burrell & Oberfell, who, by using " activated " charcoal as an absorbent, are able to obtain a much larger proportion of stable gasoline products than by any other process, larger, indeed, than that theoretically attainable by past recognized methods of testing. A condensation of carbon molecules has been suggested, but it is likely that the difference is due to mechanical features. This recent development opens up a new line of study that may influence the future of this industry.

As already stated, at present practically no treatment of gas for gasoline contents has been undertaken on a large scale outside America. In 1919 no less than 300,000,000 gallons of casing-head gasoline was produced in the United States,

being about 13% of the total gasoline production, although only a part of the gas available had been so far treated. The value of this gasoline constituted much more than the 13% of the total United States gasoline values, which later were estimated at 45% of the value of all American produced oil products in 1919, although its quantity represented but 25% of the crude produced.

From numerous tests made it is clear that the gaseous emanations of most oilfields contain products that would well repay their extraction, provided there were convenient means for their disposal, and it is this latter feature, which has probably been one of the chief hindrances to obvious savings that are annually being accentuated by the rising prices of petrol.

Occurrence and Origin of Helium.—Professional Paper No. 121, issued by the United States Geological Survey, and written by G. Sherburne Rogers, is the most complete monograph on helium yet published. It gives a detailed review of the history of the discovery of this gas, with full references, and it contains also the results of the author's studies of the occurrence of helium in natural gas. The author's brief résumé of the occurrences and theories as to origin are reproduced herewith.

Helium constitutes from 0·5 to 2% of certain nitrogen-rich natural gases in Kansas, Oklahoma, and Texas, and occurs in smaller proportions in the gases of many other districts in the United States. The gases richest in helium are confined to strata of upper and middle Pennsylvanian age and occur close to the surface, the helium content usually decreasing with increasing depth. Gases containing from 0·25 to 0·5% of helium occur in the lower Pennsylvanian (Carboniferous) of the Mid-Continent area, in the Mississippian and Silurian of Ohio, and in the Cretaceous of Montana, although in general the pre-Pennsylvanian gases are poor in helium, and the Cretaceous and Tertiary gases carry only traces or none at all. The helium-rich areas are not marked by igneous activity or by unusual structural conditions. There is no evidence as to whether or not the rocks in these districts are abnormally radio-active.

Helium has been detected in European natural gas in proportions as great as 0·38%. The richest gas was found in a deep test-hole in Alsace, probably in lower Mesozoic strata ; the Tertiary gas in this locality is very poor in helium and the Tertiary gases of Germany, Austria, Italy, and Transylvania are also poor. The helium content of these gases appears to vary roughly as their radio-activity.

A great variety of minerals have been found to contain at least traces of helium, and apparently only a few species are helium-free. Minerals rich in the radio-elements may contain several times their own volume of helium ; ordinary rock-forming minerals are usually poor. In general the amount of helium in a mineral is proportional to its radio-activity and increases with age, indicating that the helium has been generated by the decay of the radio-elements ; but certain beryls contain far more helium than can be explained in this way.

The gases of French and Belgian coal mines carry helium, and though the proportion is small the total volume emitted yearly is large. The coals themselves are very poor in the radio-elements, and helium is evidently not being generated in the coal nearly as fast as it is being emitted. There is, therefore, no evidence to connect the helium in the mine gases with radio-activity.

The gases of many European mineral springs contain helium in proportions as great as 10%. The volumes of helium emitted yearly by some of the springs represent all the helium that would be generated yearly by many tons of radium : hence this helium like that in mine gases, probably represents the overflow or leakage of a great underground accumulation. Furthermore, the proportion of helium in the gases bears no relation to their radio-activity.

Small proportions of helium occur in the gases of certain Italian fumaroles, where there is no evidence to connect it directly with radio-activity.

Helium constitutes 0·0004% of the atmosphere near the earth's surface. In the upper atmosphere its proportion is greater.

Helium is a prominent constituent of the solar chromosphere and of many nebulæ and stars, though the radio-elements have not been identified with certainty in any celestial bodies.

As the radio-elements generate helium in the course of their spontaneous disintegration, each occurrence of radio-active material connotes the presence of helium ; but the radio-elements, because of their activity, can be detected in far smaller quantities than can the helium to which they give rise. The radio-elements are very widely disseminated through terrestrial materials, being present in minute proportions in practically all minerals and rocks, in the atmosphere and in river and ocean water. Most petroleum and natural gas apparently contain some radium emanation. The helium generated by the radio-elements disseminated through ordinary rocks amounts to almost half a cubic foot per year per cubic mile of rock.

From the foregoing evidence certain broad conclusions may be drawn as follows :—

The helium in most minerals is probably of radio-active origin ; and, as the radio-elements are disseminated through ordinary rocks in proportions sufficient to generate large volumes of helium in the course of a few million years, much of the helium in rocks has probably also originated through radio-activity.

As helium is very prominent in celestial bodies, whereas the radio-elements are not, it is probable that helium can and does occur in the universe entirely apart from the radio-elements, and that these elements may be regarded as compounds of helium and lead which form only under certain conditions. Accordingly, much of the helium in the earth may never have been associated with the radio-elements and may therefore be primordial helium.

As the volumes of helium in some mineral-spring and mine gases are so large that incredible quantities of the radio-elements would be necessary to generate the helium as fast as it is emitted, it is probable that there are great stores of helium underground, the leakage or overflow of which appears in the spring and mine gases. These stores of "fossil" helium may be accumulations of the small volumes liberated by the disintegration of radio-elements through geologic time, or they may in large part be primordial. The helium in natural gas may therefore be primordial or it may have been liberated through the decay of the radio-elements. As a great volume of helium is contained in the atmosphere there is the third possibility—which is not concerned with the ultimate origin of the element—that the helium in natural gas has in some way been derived from the atmosphere.

Mining in British Guiana.—We extract the following paragraphs from the report of the Lands and Mines Department of British Guiana for the year 1920 :—

The output of gold for 1920 from all sources was 12,692 oz., of the value of £46,803, being a decrease of 3,524 oz. on the production for 1919. The decrease is due to the fact that fewer persons were engaged in the gold-mining industry than formerly owing to the high price of provisions, which rendered it more or less impracticable for the small claim holder and tributer to make a profit; also to the fact that the diggers who formerly worked gold were attracted to the diamond fields by the high price that ruled for precious stones during the early part of 1920. A number of men were also influenced to stay on the coast lands by the satisfactory rate of wages obtainable on the sugar estates and sea defence works.

An amount of 6,454 oz. was produced by placer washing, a decrease of 3,998 oz. on the production for 1919.

The Guiana Gold Company operated in the Konawaruk River with four dredges, and the Minnehaha Development Company operated with one dredge in the Mahdia Creek. The gold obtained by these two companies from dredging during the year was 6,238 oz., an increase of 1,001 oz. on the previous year's production. The Commissioner is of opinion that dredging is the most suitable method of winning gold from the larger creeks and flats with deep overburdens in the auriferous portions of the Colony. The substitution of a tax on profits in lieu of a royalty charge in the case of gold won by dredging will, it is confidently hoped, act as an incentive and, in time, when the financial slump at present existing throughout the world has passed away, mining capitalists will turn their attention to gold dredging and hydraulicking on a large scale in this Colony.

No quartz mining operation were carried out during the year. In No. 2 Mining District, however, explorations were carried out by the Minnehaha Development Company in the vicinity of "Look and Weep," Upper Minnehaha Creek, with a view of ascertaining whether the values of ore existing in that locality and the neighbourhood would warrant milling operations being carried out on a large scale. The result of such investigations were not made public by the end of the year.

During the year 234,456 diamonds, weighing 39,362 carats, of an estimated value of £211,829, were declared at the Department. Of these 144,348 stones weighing 25,898 carats were from the Mazaruni River; 54,404 diamonds weighing 9,444 carats were from the Puruni River; 22,386 diamonds weighing 2,738 carats were from the Cuyuni River, and 13,318 diamonds weighing 1,281 carats from the Potaro River. The notable features with regard to the year's production are the working of diamonds on the Potaro River, between Kangaruma and Amatuk, and the large increase in the total production for 1920, amounting to 149,990 stones weighing 22,656 carats over the output for 1919. These diamonds were all from alluvial workings and the entire output averaged six to the carat, but there were many stones of a carat and over. The sixteen largest stones presented at the Department during the year weighed respectively $21\frac{5}{16}$, $9\frac{13}{16}$, $9\frac{1}{4}$, $9\frac{1}{16}$, $8\frac{1}{2}$, $8\frac{1}{4}$, 8, $7\frac{1}{4}$, $6\frac{3}{8}$, $6\frac{1}{4}$, $5\frac{5}{16}$, $5\frac{1}{2}$, $5\frac{3}{16}$, $5\frac{1}{4}$, $5\frac{1}{4}$, $5\frac{1}{16}$ carats.

The Demerara Bauxite Company carried on mining operations at Akyma, Demerara River, throughout the year. The construction of the light railway from Akyma to Mackenzie and the erection of the crushing, washing, and drying plants at Mackenzie were completed during the year, all of which contributed to the more expeditious and economical handling of the ore. The total quantity of dehydrated ore shipped during the year was 31,379 tons.

Examinations for oil on behalf of D. E. Alves, of London, were made in the North-West District and other parts of the Colony by B. F. Macrorie and J. A. Bullbrook. Their results were not made public during the year, but it was generally understood that the opinion of the experts was unfavourable as to the occurrence of mineral oil in the Colony. It is, however, worthy of record that no prospecting bore-holes were put down and that this opinion is therefore based solely on the surface examinations made, coupled with the results of previous similar investigations by G. B. Reynolds, made in 1919.

Flotation for Rand Ores.—Interest in the application of flotation to Rand ores has been revived recently, and the paper by F. Wartenweiler, quoted in our September issue, has helped to draw attention to this subject. E. Homersham lately went to Johannesburg as representative of Minerals Separation, Ltd., and a laboratory has been opened there. Mr. Homersham gives some particulars of tests in the *South African Mining and Engineering Journal* for October 22.

(1) Crude ore from mine: Assay-value of ore, 9·9 dwt.; ore crushed to 80 mesh; value of concentrates, 65·9 dwt.; percentage of concentrate caught, 14·8; residues, 0·42 dwt.; recovery, 98·5%; cost of reagent, 7d. per ton.

(2) Slimes untreated: Assay-value of slimes, 1·34 dwt.; assay-value of concentrates caught, 7·2 dwt.; percentage of concentrates caught, 16·4%; residues, 0·20 dwt.; recovery, 88·1%; cost of reagent, 4d. per ton.

(3) Black Reef tailings; Assay of crude sample, 2·45 dwt.; assay-value of concentrates, 24·6 dwt.; percentage of concentrates caught, 8·6%; residues, 0·42 dwt.; recovery, 86·3%; cost of reagent, 8d. per ton.

(4) Sand residues from Rand ore: (1) The first tests were on sand as received without further grinding. There was no difficulty in concentrating by flotation the free mineral consisting of iron pyrites. The concentrates averaged 10 dwt. in value, and were about 6% of the bulk treated. The original value of sand in this test was 1·4 dwt. and the residues averaged 0·85 dwt. It was quite clear that a large proportion of gold was locked up in sands and could only be floated by further grinding. (2) The next test was made as follows: Assay of crude sand, 1·75 dwt.; concentrates, 12·6 dwt.; percentage of concentrates caught, 10·3; residues, 0·45 dwt.; recovery by flotation, 74·1%; crushing, 80 mesh; average cost of reagents 4d. per ton.

In view of the above results, even allowing for the cost of regrinding sand, it appears probable that these particular sand residues can be profitably retreated by flotation.

A fairly large scale test of 1,870 lb. run in London recently gave a 0·55 dwt. residue on a grade of ore assaying 22 dwt. If the ore had been of a lower grade, undoubtedly a far lower residue would have been obtained; as it is, this result indicates a recovery of from 96 to 98%. From tests done

in Johannesburg and in London it appears probable that on a 4 dwt. ore a residue of 0·15 to 0·2 dwt. may be looked for, the residue rising more or less slowly as higher grade ore is treated.

It is believed that the process, if applied to current reduction works, would mean a large saving in working costs. Instead of treating the whole of the crude ore by cyanide, it is believed from the results obtained up to date that a 10% concentrate can be obtained containing from 93 to 97% of the gold in the ore, and that this concentrate can be easily treated by the ordinary cyanide method.

Nickel Metallurgy.—The *Bulletin* of the Canadian Institute of Mining and Metallurgy for November contains two brief notes on points relating to the smelting of nickel-copper ores in the Sudbury district.

William Kent writes on a false chute for skimming converters used at the smelter of the International Nickel Company. With the large basic-lined copper-converters now in use, the common practice is to do all charging, skimming, and casting through the throat of the converter. Most of these converters are rotated by means of electrically operated worm gear, and it is possible to turn them through a complete revolution. The converters at the International Nickel Company's smelter, however, are turned by means of cables actuated by pistons in horizontal cylinders, and hence the extent of the rotation is limited by the stroke of the piston. Owing to this method of rotation, the skimming and casting have to be done through a chute at the side of the shell. The limited extent of the rotation also renders it necessary to have the opening through the shell, at this chute, about 30 in. high, in order to be able to carry the converter full of matte while blowing, and to be able to drain out the last of the finished matte when casting. Before charging the converter the opening in the shell is blocked up with magnesite brick to within about 6 in. of the top, the chute outside being filled with clay to the same height. A cake of clay covers the remaining opening during the blow and is removed when ready to skim. During the successive skims the slag running over the clay in the chutes permeates it and bakes it to such an extent that a very hard mass is formed. When ready to cast, about three-quarters of the matte is poured from the converter in the same way, tending to still further harden the clay. To drain out the final quarter of the matte, it is necessary to dig the clay out of the chute and remove the bricks from the lower part of the breast opening. The removal of the clay entailed a good deal of hard work with bars and hammers, and, in addition, caused considerable delay. All this is now obviated by the use of a false chute, which fits just inside the fixed chute and does not interfere with the regular procedure in any way. The false chute is provided with short chains at the corners, and when the time comes for the removal of the clay, the crane comes along and lifts out both chute and clay, leaving the breast exposed. It is then only necessary to remove the bricks and complete the casting. When cold the false chute is easily cleaned out and is again ready for use.

R. J. Gill read a paper on improvements to settlers at the British America Nickel Corporation's smelter at Nickleton. The settler practice at the British America smelter is somewhat unusual for the Sudbury district. A great portion of the matte is tapped from the settler by means of so-called syphons. The principle is similar to that of the Orford settler, or of the Watson settler. The last-named is a modification of the Orford used at the Ladysmith plant of the Tyee Copper Company. At Nickleton the 16 by 30 ft. settlers are lined with chrome brick. The floor is made up of three courses of chrome brick laid on 6 in. of fireclay. The top and bottom courses are laid on edge, and the intermediate course flat. The walls are three bricks thick, the outside row being firebrick. An additional row of chrome brick was added for part of the height of the wall, as the settler must always contain about 10 in. of matte. The front wall was also increased in thickness to about 22 in. The shell of the settler is ½ in. steel plate. Originally there were four matte tap-holes at the front and two slag overflow openings at the back. To convert the settler into a syphon settler a wall of chrome brick 15 in. thick was built across the settler, a little over 2 ft. from the front wall. A wall at right angles to this divided the portion thus cut off into two wells. For admitting the matte an opening approximately 24 in. wide by 8 in. high was left in each of these wells at the floor of the settler. Thus, so long as the matte level in the main settler is kept above the opening, no slag can enter the well. An opening was made in the front wall just deep enough to ensure that when the bath in the settler is raised by blocking the slag overflow, the matte will flow out of the well into a launder from the top of the settler. The flow of matte is stopped without difficulty by opening the slag overflow and letting the bath down. Two of the original tap-holes are retained, one from each well. Magnesite blocks, 8 by 8 by 8 in., are set in these, without a cooling jacket of any kind. They are held in place by cast-iron plates secured by wedges. All the matte drawn from the settler must pass through the openings into the bottom of the wells; but after several months of service the brick in the arch over the opening showed little sign of wear. Owing to the large quantity of matte and the inferior quality of the refractories at hand, it was extremely difficult to keep the tap-holes in good condition. This syphon was devised to overcome this trouble, and has been a complete success. The tap-holes are now kept open more for use in case of an emergency than for any other reason. The matte well shows no tendency to chill, due probably to the fact that it is contained in the settler; the only loss of heat by radiation is through the thick front wall.

Treatment of Zinc Residues. — *Chemical Engineering and Mining Review* (Melbourne) for August gives some particulars of the direct method of dissolving fume in acid adopted in the treatment of zinc residues at the works of the Electrolytic Zinc Company of Australia, Risdon, Tasmania. In the electrolytic method of treatment the concentrates are first roasted and then leached with sulphuric acid solution. The residue left after the leaching operation contains a certain amount of zinc, together with lead and other metals, and it has been customary to treat this residue for the formation of fume by mixing it with a reducing agent, such as coke, and subjecting the mixture to a blast of air on a Wetherill grate or some such suitable furnace. This fume is sometimes sold as a leaded zinc pigment, but is often leached with sulphuric acid to produce electrolytic zinc. The method of fuming as applied to the residue from the leaching operation has also been applied directly to the ore either roasted or unroasted. Various patents have been taken out for processes aiming at

the conversion of zinc into fume, and its collection therefrom. In 1904 (Commonwealth 264) J. C. Clancy proposed blowing sulphide ore into a highly heated chamber to transform the zinc sulphide into oxide, which would be condensed and leached out with H_2SO_4. In 1907 Hommel and Sulman (Commonwealth 10,362) patented an elaborate process in which the sulphide ore is roasted and mixed with coal and suitable fluxes, placed in a furnace on heated fuel, and air blown through. The zinc is recovered from the condensed fume by leaching with sulphuric acid. J. H. & P. M. Gillies (Commonwealth 171) in 1916 proposed to fume lead and zinc, leaching the zinc from the condensed fume with H_2SO_4. Another patent (Commonwealth 6,456) taken out in 1918 by the same investigators, related to a similar leaching process. Laist, of Anaconda, patented a combination leaching and smelting process for electrolytic zinc residues in 1917 (Commonwealth 6,018), in which the residues are dried, mixed with fine coal, and smelted to produce a matte, slag, and fume containing the lead and zinc, which is collected and leached with dilute H_2SO_4 for the recovery of the zinc. In all these methods, however, the expensive means of collection by bag-houses or electrical precipitation have been involved. In cases where it is subsequently intended to leach the fume, it would be a matter of great benefit if the above methods of treatment were modified so that in this fuming operation the bag-house or similar collecting means were replaced by a cheaper method. Experiments have accordingly been carried out by the Electrolytic Zinc Co., at Risdon, with a view to evolving a process by means of which the fume may be directly leached without the intervention of a bag-house or other collecting means. The resulting new treatment, which is proposed to be put into operation on a large scale, consists in passing fume from the Wetherill furnaces upward through a tower checkered with suitable packing to give a large area on contact and to prevent accumulations of the insoluble portion of the fume. Down this tower H_2SO_4 solution (spent electrolyte) is caused to flow against the ascent of the fume so as to be brought into intimate contact with them, causing the soluble constituents, which consist principally of zinc compounds, to be dissolved in the descending solution, which is run into a receptacle at the bottom of the tower. The solution and solid residue thus collected are treated by known metallurgical methods for the recovery of their valuable metal contents.

SHORT NOTICES

Rapidity of Boring. In the *Iron and Coal Trades' Review* for November 11, A. E. Ritchie gives comparisons between British, German, and American boring practice, exemplifying his points by reference to bore-holes in the Kent coalfield. British boring was too slow, and on the other hand, German boring was too rapid for securing satisfactory records of the strata passed through. The Sullivan Machinery Co., of Chicago, has done rapid work in this country, and though not quite so rapid as the German firms, gives better geological records.

Diamond - Drilling. In the *Colliery Guardian* for November 4, J. A. MacVicar gives some records of experience in boring in the United Kingdom by means of the Sullivan diamond-drill.

Ventilation at Broken Hill. — At the meeting of the Australasian Institute of Mining and Metallurgy, held in August, a paper was presented by R. T. Slee, describing the ventilation system at the Broken Hill Proprietary mine.

Acidity of Mine Waters. In a paper published in the September issue of the *Journal* of the Chemical, Metallurgical, and Mining Society of South Africa, F. W. Watson and R. A. Cooper revive the question of the neutralization of acids in mine waters.

Air-Lift for Tailings. In the *Engineering and Mining Journal* for November 19, H. G. S. Anderson describes the air-lift for raising tailing at the Chino copper mine, New Mexico.

Broken Hill South. — At the meeting of the Australasian Institute of Mining and Metallurgy held in August, W. E. Wainwright and J. C. Cunningham presented a paper describing the new concentration plant at the Broken Hill South mine.

Filter-Presses. The *Journal of Industrial and Engineering Chemistry* for November contains reports of a great many articles on filter-pressing practice presented at the meeting of the American Chemical Society held in September.

Chloridizing-Volatilization.—In the *Engineering and Mining Journal* for November 2, H. R. Layng gives some instructions for improvements in the methods of conducting the chloridizing volatilization process, in particular with the object of preventing accretions.

Sulphuric Acid.—In *Chemical and Metallurgical Engineering* for November 9, A. M. Fairlie commences a series of articles on modern improvements in the method of producing sulphuric acid.

Uranium Steel. In *Chemical and Metallurgical Engineering* for October 26, H. S. Foote discusses the properties imparted to steel by varying percentages of uranium.

Chromium Steel. In *Chemical and Metallurgical Engineering* for November 2, F. P. Zimmerli gives a historical bibliography of chromium steels. This bibliography gives a brief abstract of most of the entries.

Determination of Chromium. The *Journal of Industrial and Engineering Chemistry* for November contains an article by G. L. Kelly and J. A. Wiley on the determination of chromium in ferro-chromium by electrometric titration.

Radium. In *Chemical and Metallurgical Engineering* for November 2, H. D. d'Aguiar describes the method of producing radium compounds in America.

Cornish Geology.—The *Geological Magazine* for November contains a paper by E. H. Davison on the primary zones of Cornish lodes.

Grecian Magnesite.—In the *Engineering and Mining Journal* for November 12, H. C. Boydell gives an account of the magnesite deposits in the island of Eubœa, Greece.

Tin in Queensland. The *Queensland Government Mining Journal* for September contains a report by E. C. Saint-Smith, Government Geologist, on the Ewan Tin Syndicate's properties in the Kangaroo Hills district.

Uganda. — The *Geographical Journal* for November contains an account of the Lake Albert Rift Valley, Uganda, by E. J. Wayland, Government Geologist.

Low-Temperature Carbonization. The *Iron and Coal Trades Review* for November 11 publishes a report made by Sir Percy Girouard on the process

[illegible] plant of the Low Temperature Carbonization Co., Ltd., at Barnsley, the present company that [illegible]

Coalite. *Engineering* for October 28 gives an illustrated description of the plant of Low Temperature Carbonization, Ltd., at Barnsley, which makes coalite and various by-products.

Venezuelan Petroleum. The *Engineering and Mining Journal* for November 12 publishes an official report by A. H. Redfield on the petroleum industry of Venezuela during the year 1920.

Colorado Shale Oils. In *Chemical and Metallurgical Engineering* for October 19 and 26, A. J. Frank gives an account of the oils obtainable from Colorado shales.

Gas from Wood Refuse. The *Engineer* for November 18 describes a gas producer designed for using waste wood, made by Ruston & Hornsby, Ltd., of Lincoln.

C. W. Purington. The *Engineering and Mining Journal* for November 5 gives a brief biography of C. W. Purington.

Alfred James.—The *Engineering and Mining Journal* for November 19 contains a biographical notice of Alfred James.

RECENT PATENTS PUBLISHED

☛ *A copy of the specification of any of the patents mentioned in this column can be obtained by sending 1s. to the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. 2, with a note of the number and year of the patent.*

6,921 of 1920 (169,467). CHEMISCHE FABRIK RHENANIA, Aachen, Germany. Method of recovering sulphur from sulphuretted hydrogen.

10,078 of 1920 (169,473). J. & A. ROSS, Uddington, Scotland. Signalling apparatus for mines.

10,293 of 1920 (170,026). C. E. CORNELIUS, Stockholm. Furnace for treating zinc dust for the production of spelter.

16,587 of 1920 (169,764). E. E. NAEF, Nottingham. In the manufacture of copper the treatment of finely divided copper sulphides with solid caustic soda or potash, or mixtures thereof with any or all of the following: sodium carbonate, common salt, sodium sulphate, sodium sulphide, calcium oxide and hydroxide, at temperatures generally from 300° to 800° C., with or without the addition of finely divided coal, or in presence of hydrogen and gases containing such, or in presence of both coal and hydrogen.

18,669 of 1920 (146,814). MASCHINENFABRIK WESTFALIA, Gelsenkirchen, Germany. A channelling rod for mining machines of the rod type.

18,979 of 1920 (147,030). E. H. WESTLING, San Francisco. Method for producing pure manganese dioxide.

19,253 of 1920 (147,186). P. SCHERMULY, Frankfurt-am-Main, Germany. A new form of divining rod.

19,363 of 1920 (147,457). AMPERE GESELLSCHAFT, Berlin. Method of producing a tungsten-iron alloy used in the jewellery trade.

19,364 of 1920 (147,458). AMPERE GESELLSCHAFT, Berlin. Method of producing ferrochromium low in carbon.

19,755 of 1920 (147,752). W. P. THOMPSON, Liverpool. Method of making white lead.

19,959 of 1920 (170,082). METALLBANK and METALLURGISCHE GESELLSCHAFT, Frankfurt-am-Main, Germany. Method of producing zinc oxide by precipitation from sulphate solutions sufficiently free from sulphate of lime to make it suitable for smelting for zinc.

20,248 of 1920 (148,334). M. SCHLÖTTER, Berlin. An electroplating process for producing a firmly adhering deposit of tin.

20,522 of 1920 (148,539). SPRENGLUFT GESELLSCHAFT, Charlottenburg, Germany. Method of making cartridges of carbonaceous matter suitable for absorbing liquid air, to be used for blasting purposes.

20,526 of 1920 (148,543). A. R. AHRENDT & Co., Berlin. Apparatus for producing a respirable air from liquid air.

20,518 of 1920 (148,535). C. A. BALDUS and A. KOWASTCH, Charlottenburg, Germany. Fuses for igniting blasting cartridges in which liquid aid is used.

20,525 of 1920 (148,542). P. MEFFERT, Coblenz, Germany. Improved receptacles for holding blasting cartridges containing liquid air.

20,885 of 1920 (170,100). L. H. DIEHL, Darmstadt, Germany. The treatment of material containing iron and zinc in a blast-furnace, so as to recover the zinc by volatilization and the iron by reduction and melting.

21,787 of 1920 (170,404). L. A. LEVY and R. H. DAVIS, London. A respirator useful in atmospheres containing carbonic oxide.

21,988 of 1920 (170,651). W. E. NETTLE, P. SELBY, J. BLYTHE, and J. H. HOLMAN, Johannesburg. Mechanism for supplying water to rock-drills.

25,892 of 1920 (170,474). BADISCHE ANILIN & SODA FABRIK, Ludwigshafen am Rhein. A fertilizer consisting of ammonium sulphate and ammonium nitrate. [This mixture is said to be explosive and to have caused the disaster at Oppau.]

29,801 of 1920 (163,023). RHENISCH-NASSAUISCHE BERGWERKS UND HÜTTEN GESELLSCHAFT, Stolberg, Rhineland, Germany. Improved methods of rabbling in Spirlet roasting furnaces.

13,621 of 1921 (164,725). SOCIÉTÉ D'ELECTRO-CHIMIE ET D'ELECTRO-METALLURGIQUE, Paris. Improvements in the electrolytic method of producing iron.

NEW BOOKS, PAMPHLETS, Etc.

☛ Copies of the books, etc., mentioned below can be obtained through the Technical Bookshop of *The Mining Magazine*, 724, Salisbury House, London Wall, E.C. 2.

Catalogue of British Scientific and Technical Books. Prepared by a Committee of the British Science Guild. Cloth, octavo, 390 pages. Price 10s. net. London: The British Science Guild, 6, John Street, Adelphi, London, W.C. 2. This is an ambitious work, but covers far too much ground, ranging from dermatology and aeronautics to textiles and tobacco culture. Then, again, a catalogue is of no use to English readers unless it includes American books. The classification is by no means perfect, and the preface acknowledges this difficulty; but we did not expect to find Julian and Smart's Cyaniding Gold and Silver Ores under the heading of ore-dressing.

Preliminary Report on Petroleum in Alaska. By G. C. MARTIN. Bulletin 719 of the United States Geological Survey.

Mineral Industry of the British Empire: Phosphates. Pamphlet. 70 pages. Price 2s. net. London: Imperial Mineral Resources Bureau.

Geology and Mineral Resources of the Serb-Croat-Slovene State. By D. A. WRAY. Foolscap, paper covers, 110 pages, with maps and other illustrations. Price 3s. 6d. net. London: The Department of Overseas Trade. This is a report prepared for the British Economic Mission to Serbia, by a member of the Geological Survey of Great Britain.

Practical Chemistry of Coal. By A. E. FINDLEY and R. WIGGINGTON. Cloth, octavo, 150 pages, illustrated. Price 12s. 6d. London: Benn Brothers, Ltd.

Geological Survey of West Australia. Bulletin 79: Mining Geology of Comet Vale and Goongarrie, by J. T. JUTSON; Bulletin 80: Mining Centres of Quinn's and Jasper Hill, by F. R. FELDTMANN; Bulletin 81: The Warriedar Gold-Mining Centre, by F. R. FELDTMANN.

Permeation of Oxygen Breathing Apparatus by Gases and Vapours. By A. C. FIELDNER, S. H. KATZ, and S. P. KINNEY. Technical Paper 272 of the United States Bureau of Mines.

Miners' Consumption in the Mines of Butte, Montana. By D. HARRINGTON and A. J. LANZA. Technical Paper 260 of the United States Bureau of Mines.

Relative Safety of Brass, Copper, and Steel Gauzes in Miners' Flame Safety Lamps. By L. C. ILSLEY and A. B. HOOKER. Technical Paper 228 of the United States Bureau of Mines.

Income Tax Guide, 1921. By H. W. PALMER. Price 1s. net. London: *The Financial Times.* The incidence of the income tax does not become any the less inexplicable, nor does the tax itself grow any less burdensome, and we should be grateful to those who try to help us to bear and to understand one of the most serious of life's many troubles. The management of the *Financial Times* have produced a new and revised edition of their *Income Tax Guide*, which tells us all about income, excess profits, and corporation taxes, what to pay, and how to obtain relief, with tables and examples. The booklet is based throughout on official data, is thoroughly up to date, and is so written that it may be understood even by those to whom the mere mention of income tax involves an immediate and dermanent clouding of the brain.

COMPANY REPORTS

Weardale Lead.—This company has been working lead mines in Weardale, County Durham, since 1883. The control is in Newcastle-on-Tyne, Professor Henry Louis is consulting engineer, and H. S. Willis is manager. The report for the year ended September 30 shows that owing to the fall in the price of lead it became necessary to restrict operations to the more profitable places. In addition, the mines were entirely idle for twelve weeks owing to the coal strike. The output of lead concentrate was 1,563 tons, and of fluor-spar 6,870 tons, comparing with 2,774 tons and 9,374 tons during the previous year. The accounts show a loss of £10,828 on working account, and £8,229 has to be provided for income tax. On the other hand, £8,821 previously paid as excess profits duty has been recovered. The year began with a credit balance of £4,005, and £2,936 was received as dividends on investments. The year ended with a deficit of £3,286. The question of wages has been frequently discussed with the men, and the latter have agreed to reductions in keeping with the general state of the labour market. Some substantial economies have been effected by the installation of electric haulage and new dressing plant. These two facts encourage the directors in the belief that profits will be made once more in the early future.

Burma Corporation.—The history of the various companies that have successively operated the lead-zinc-copper-silver deposits at Bawdwin, Northern Shan States, are already sufficiently well known, so that no reference to earlier reports is necessary here. Suffice it to say that the property was transferred in December, 1919, to a company registered in Rangoon. The report now issued by this company covers the year ended December, 1920. During this period 93,038 tons of ore, averaging 38·1% lead, 23·6% zinc, 0·4% copper, and 37·3 oz. silver per ton, was sent to the smelter; and 30,424 tons, averaging 33·8% lead, 24·5% zinc, 0·2% copper, and 31·7 oz. silver, was sent to the concentrators for the separation of the sulphides. The first unit of the water-concentration plant was started in July, 1920, but owing to the scarcity of suitable labour only a few machines were started at a time. In fact the work throughout the year was in the nature of training labour. The flotation plant was not started until 1921. During 1920 the smelter treated 136,450 tons of material, averaging 29·57%, 15·5% zinc, and 26·72 oz. silver per ton, and 28,484 tons of lead bullion was produced. The refinery produced 23,821 tons of lead and 2,869,727 oz. of silver. The reserve is estimated at 4,429,458 tons, averaging 25·3% lead, 17·7% zinc, and 23·2 oz. silver per ton; of this total 335,681 tons is copper ore averaging 11% copper, 12·8% lead, 7·7% zinc, and 23·2 oz. silver. Owing to the depressed position of the metal market, it has not been possible to proceed with various expansions contemplated, and it has been necessary to continue the policy of obtaining an income by the treatment of the sections of ore richest in lead and silver. The contemplated yearly output is 45,000 tons of lead and 4,500,000 oz. of silver. The construction of the zinc works in India has been suspended owing to the Government withdrawing its financial help and owing to the Tata Company being desirous of limiting its participation. Also the construction of the new smelter is deferred, and the development of the Namma coalfield. For the first time in the reports the labour position is mentioned, and the conditions revealed are not calculated to comfort the shareholders. Reference to this matter is made elsewhere in this issue. The report also mentions that the engagement of R. G. Hall as resident-manager was not renewed when his term expired in September, 1921, and that P. E. Marmion has been appointed to the position. The accounts show receipts of £1,081,380 (with the rupee at 1s. 4d.) derived from the sale of lead and silver, and a net profit of £246,770, which was carried forward.

North Broken Hill.—The report now issued covers the year ended June 30, 1921. Operations were resumed on a restricted scale when the long strike terminated on November 10, 1920, the restriction being necessary owing to the low price of and poor demand for lead, together with the high wages and costs and the limited capacity for smelting. The result of the operations from November to the end of the company's financial year was a loss of £62,242, without any provision for depreciation, taxes, or royalty. After the fire at the Port Pirie smelters of the Broken Hill

As stated on January 25, lead concentrate was sent to the Cockle Creek works of the Sulphide Corporation for treatment. During the year 43,021 tons of ore was raised from the mine, and 32,300 tons was treated at the concentrators, which produced 6,461 tons of lead concentrate, averaging 65.5% lead, 7.3% zinc, and 28.4 oz. silver per ton, and 6,010 tons of zinc concentrate averaging 48.1% zinc, 7.4% lead, and 9.6 oz. silver. The old contract by which the zinc tailing was delivered to the Amalgamated Zinc (De Bavay's) for treatment expired on April 30, 1919, a few days before the commencement of the long strike. On the resumption of operations, the company's new plant was started, and both lead and zinc concentrates are now produced. As already mentioned, the year's work ended in a loss of £62,242, but as there was another item of income, £70,370, derived from the sale of concentrates produced before the strike, there was an actual credit balance of £8,128.

Bisichi Tin.—This company was formed in 1910 to acquire alluvial tin properties south-east of Bukeru, on the Bauchi Plateau, Nigeria. Toward the end of 1920 the properties of adjoining companies, the Forum, Ninghi, and Northern Nigeria Trust, were absorbed with the object of securing greater economy in administration. The report now issued covers the year 1920. During this time the output at the Bisichi section was 133 tons of tin concentrate, and the output at the acquired properties was 128 tons. The working result was a loss of £2,498. Accompanying the directors' report is one by Lake & Currie, engineers to the company, dated October 31, 1921. H. E. Nicholls, partner in this firm, has recently returned from a visit to the properties extending over five months. This report shows that on E.P.L. 1060 of the Forum section prospecting by bores and pits has recently proved ground estimated to contain 6,747 tons of cassiterite. This discovery will have an important bearing on the future operations of the company.

Luipaard's Vlei.—This company has operated property in the far west Rand since 1888, and the control is now with the Hamilton-Ehrlich group. Operations have never been very profitable, and no dividends have been paid since 1916. The report for the year ended June 30 last shows that 206,695 tons of ore was sent to the mill, where 48,152 oz. of gold or 4.66 dwt. per ton was extracted by amalgamation and cyaniding. The gold was sold for £269,867, or 26s. 1d. per ton, the price realized averaging 112s. 1d. per oz. The working costs was £253,712, or 24s 6d. per ton, leaving a working profit of £16,154, or 1s. 7d. per ton. Other items of revenue brought the profit to £22,960, from which is deducted £17,584 allowed for depreciation. The reserve is estimated at 624,766 tons, a reduction of 77,081 tons on the year. Additional areas on the west have been acquired during the year, and these are estimated to contain 260,000 tons of ore. Connexion with these deposits is being made from the main workings on the 12th, 14th, and 17th levels. The position at the mine depends on the gold premium and on the prospect of a reduction in white wages. It is not considered likely that the cost of stores will drop appreciably.

Simmer & Jack.—This company belongs to the Consolidated Gold Fields group, and has worked an outcrop mine in the Central Rand since 1887. For the last six years or so the dividends have been small, and there is not much remaining ground to be developed other than that recently acquired from the Simmer Deep and Jupiter companies. The report for the year ended June 30 last shows that 784,200 tons of ore was mined, and after the rejection of waste, 702,000 tons was sent to the mill. The yield of gold by amalgamation was 93,474 oz., and by cyanide 67,247 oz.; in addition, 86 oz. was recovered in by-products, bringing the total to 160,807 oz. The revenue from the sale of gold was £890,831, of which £211,766 accrued from premium. The working cost was £771,580, leaving a working profit of £119,253. The yield per ton at par was 19s. 4d., and the premium 6s., making a total yield of 25s. 4d. The cost per ton was 21s. 11d., leaving a profit of 3s. 5d. It will be seen that without the premium a loss of 2s. 7d. per ton would have been incurred. The shareholders received £75,000, the dividend being at the rate of 2½%. During the year the development disclosed payable ore over 594 ft., averaging 13.7 dwt. over 33 in. The reserve at June 30 was estimated at 1,081,000 tons, averaging 5.71 dwt. over 76 in. The sinking of the Rhodes incline shaft has been completed to the 39th level. The ore from the claims acquired from the Simmer Deep and Jupiter will be hoisted through this shaft.

Glynn's Lydenburg.—This company has worked gold mines in the Lydenburg district of the Transvaal since 1895. The Transvaal Consolidated Land and Exploration Co., Ltd., are the secretaries, and the Central Mining and Investment Corporation, Ltd., has technical control. The report for the year ended July 31 shows that 40,140 tons of ore was sent to the mill, and that 5,957 oz. of gold was extracted by amalgamation and 9,347 oz. by cyanide, making a total of 15,304 oz., equal to 7.62 dwt. per ton. The revenue derived from the sale of the gold was £86,358, including premium, and the working cost was £70,853, leaving a working profit of £15,504. It will be seen that but for the premium there would have been a loss. Dividends at the rate of 8¾%, absorbing £14,875, have been distributed. The directors have adopted a policy involving a considerable increase in prospecting and development, and it is probable that for some time all the profits will be allocated to this purpose.

Gaika Gold.—This company was formed by the Rhodesian Exploration and Development Co., in 1902, to work a gold property near the Globe and Phœnix, in Rhodesia. Control passed to the Gold Fields Rhodesian Development Company in 1912. The report for the year ended June 30 shows that 40,127 tons of ore was raised and treated, yielding 9,156 oz. of gold by amalgamation and 5,824 oz. by cyanide, a total of 14,980 oz. The income derived from the sale of the gold was £82,580, of which about £19,000 represented premium. The profit was £32,613, and £34,186 has been distributed as dividend, being at the rate of 12½%. The ore reserve at June 30 was estimated at 73,000 tons, averaging 13.2 dwt. per ton, as compared with 64,000 tons, averaging 15.7 dwt. the year before. There has been much discussion lately as to whether it would not be possible to increase the tonnage and assay-value of the ore treated, but Cyril E. Parsons, the consulting engineer, is against such a policy, as he holds that the position does not warrant such an increase. At the meeting of shareholders held last month the agitators for an increase carried the day, and their leader was elected to the board. Reference to this matter is made in the Review of Mining.

BISICHI TIN COMPANY, LTD.

Directors: James Gardiner (*Chairman*), W. S. Coutts, W. Graham, H. E. Nicholls, A. H. Young. *Engineers:* Lake & Currie. *Secretary:* W. W. Evans. *Office:* 33, Cornhill, London, E.C. 3. *Formed* 1910; absorbed the Forum River, Ninghi, and Northern Nigeria Trust companies in 1920. *Capital Issued:* £372,039.

Business: Operates alluvial tin properties on the Bauchi Plateau, Nigeria.

The tenth annual general meeting of the Bisichi Tin Company (Nigeria), Ltd., was held on November 30 at the Cannon Street Hotel, London, E.C., Mr. James Gardiner (Chairman of the company) presiding.

The Chairman, in moving the adoption of the report and accounts for the year 1920, said that the delay in submitting these was due entirely to the protracted nature of the liquidation of the accounts of the absorbed companies, the final audit of which had only just been completed. The issued capital now stood at £372,039, the increase being due to the purchase consideration for the absorbed companies, full details of which were issued at the time the amalgamation was carried into effect. The item under the heading contingent liability represented a liability not in cash but in fully-paid shares in, and contingent only on, the Lancarrow property in Cornwall being floated as a separate concern. Although the item had been inserted at the request of the auditors it was in reality no liability at all. The exploration account showed an increase of about £8,500, but this was money well spent, and the progressive policy adopted by the directors in respect of acquiring new areas had been fully justified by the very large additions to reserves.

There were remarkable developments which had taken place since the occasion of their last meeting. This was dealt with in the report of their engineers, Messrs. Lake & Currie, which, for the purpose of giving the fullest and latest available information, had been brought as nearly up to date as possible. At the last annual meeting reference was made to an area then held jointly with the Forum Company, and which was now, of course, wholly their own property, which promised to develop into one of considerable value, and it was with the greatest satisfaction that he was now able to tell shareholders that these anticipations had not only been realized, but that the discoveries had been so highly important as to exceed even their most sanguine expectations. The ground in question held under exclusive prospecting licence 1060 was large in extent; to be exact, it had an area of 3·87 square miles. On a small portion of this there had already been proved by prospecting no less than 6,747 tons of concentrates (70% metal), the gross value of which, even at the price of tin ruling to-day—namely, £163 per ton—was no less than £750,000 sterling. Attention was drawn by their engineers to the fact that this was a continuous deposit, and in that respect, as far as they were aware, the largest of its nature yet discovered. At any rate, it was one of the chief, if not the most important, of the discoveries made in Nigeria. The possibilities of this area were by no means exhausted, and he had every confidence that prospecting, which was still being carried out, would eventually substantially increase the figure given.

While this discovery was, of course, the most important development during the last year, nevertheless the additions to the reserves proved on other sections of their property were by no means negligible, and a total of nearly 11,000 tons of proved reserves, with a gross value at to-day's price of the metal of almost £1,250,000 sterling, was a figure which could be viewed with complete satisfaction.

One other point was the fact that, apart from the potentialities of the very large areas of new ground yet to be tested, the possibilities of the old leases were by no means exhausted, for already in several instances payable ground had been found to exist where it was least expected. In the statement of reserves in the report no allowance was made for ground known to be payable but not sufficiently tested to enable definite calculations to be made, and therefore the figure given might be taken as a strictly conservative one. Although work had been restricted in other directions, prospecting was being continued, and also the development of the various areas by construction of dams and leats was in force, so that they might be in a position to increase output and take advantage of any improvement in the price of the metal.

Another subject to which he wished to refer was one which affected not only their own company, but also the industry as a whole. Just as in the Malay States, where, with the working out of the shallower deposits, hand labour had perforce to be superseded by mechanical appliances, so was history repeating itself in the case of Nigeria. Here, again, the more easily won tin was becoming exhausted, and what might be termed the transition stage in methods had now been reached. In future mechanical methods must be increasingly adopted, and with this would arise the serious question of motive power. This could only be effected by three agencies—namely oil fuel, coal, and water-power, the first of which was almost ruled out by its prohibitive cost, while cheap coal from the Udi field would not be available until the mining field had been connected with it by the railway now under construction, a matter, however, of some years yet. There remained the third source, and those companies who had water to generate power were singularly fortunate, and it was therefore a matter of congratulation that their own properties were very favourably situated in this respect, a fact which would undoubtedly facilitate the economic development and exploitation of their very extensive areas of ground.

In conclusion, without wishing to assume the role of prophet—indeed, he would be a rash man who would indulge in prophecies under existing circumstances—he ventured to say that when the present world-wide state of depression came to an end, as come it must, tin would be one of the first commodities to be favourably affected by the improvement, and that their company would be in a position to reap its full share of the benefits resulting from an improvement in conditions.

Mr. W. S. Coutts seconded the resolution, and it was carried unanimously.

IDA H. MINING CO., LTD.

Directors: Sir George C. Denton (*Chairman*), John Waddington, St. John Winne, A. O. Cautley. *Secretary*: F. S. [illegible]. *Office*: Blomfield House, London Wall, London, E.C. 2. *Formed* 1900; reconstructed 1920. *Capital Issued*: £46,742 in shares of 5s. each.

Business: Conducts exploration work in Nigeria.

The first annual general meeting of the Ida H. Mining Co., Ltd., was held on November 29, at Blomfield House, London, E.C. 2, Sir George C. Denton (Chairman of the company) presiding.

The Chairman, in moving the adoption of the report and accounts for the year ended April 30 last, said the directors' views on the question of the Monguna area were fully set out in the report. Personally, he thought Mr. Wham showed that a satisfactory condition of affairs existed on that part of their property, and he believed there was a good future for the company there, provided that the price of tin did not fall lower than it was at present. If, as time went on, circumstances justified the erection of the pipe-line recommended by Mr. Wham, he had every reason to believe that the development of this area would prove a success. They would notice from the report that they had some ten tons of tin in Nigeria. So far they had not sold it, because the price of the metal had been very low, but as, even at the present rate, it should realize between £700 and £800, it might be desirable to have it sent home at an early date.

He wished he could give as good an account of the Damo area. They would no doubt remember that when the Ida H. Mining Company was formed the directors had before them excellent reports on it. Unfortunately, the manager whom they sent out, and who came to them with very good testimonials, had failed to discover tin in payable quantities. Naturally, the directors had done their best to investigate matters, with the result that they found views of a very conflicting nature were held on the point. After careful inquiry the directors were not satisfied that the manager might not have been too hasty in his conclusion, and for that reason it was their intention to adopt the course mentioned in their report.

Shareholders would be aware that there were said to be very favourable prospects for gold mining in Nigeria, and in this connexion they had, through the good offices of Mr. John Waddington, been fortunate enough to secure a year's option over one square mile in what was known as the Jebba district. From information that had reached him he believed that this ground had a future before it, and he was told that an eminent geologist had formed a very favourable opinion of it and had even gone so far as to say that if the quartz shown him came from Jebba—which it did—it was the most important discovery that had ever happened in Nigeria. They had not been behindhand in this matter, and he believed that Ida H., being one of the first in the field, had the right to expect that its square mile would be very favourably situated, as selections were made in the order in which prospectors commenced operations.

So far he had refrained from referring to the very depressed conditions of all commercial undertakings at the present time and, having regard to the cost of production, the ruinously low price tin was realizing. It was a little better now, and they hoped the trouble might be only temporary and that there would be a further improvement in the tin market at an early date, but low prices had gone on for some time now and they seemed rather firmly established, he was sorry to say. It was true that the Nigerian Government, recognizing the position, had granted concessions in respect of royalties and rents which must be of great assistance to the tin industry and they were thankful to them for what they have done, but—and it was a big "but"—the railway freights were still very high—exorbitantly so, he was told—when compared with those ruling in other colonies. At present he was afraid there was not much use in agitating for a reduction, but the matter must not be lost sight of and if a favourable opportunity arose for a representation to the Government advantage should be at once taken of it and the Colonial Office approached.

Mr. C. G. Lush, the company's consulting engineer, said that the report on Damo was most disappointing to himself, because they had such men as Mr. Carpenter, who worked the property on tribute and who found it highly payable; they had Mr. Roche, a very successful miner, working his own property in Nigeria, and who had been there for some 15 years, and who in consequence of his working his own property was worth more than he was—he had made £20,000 to £30,000 in Nigeria through working tin economically—and who said this was a very good property; and then they had Mr. Speed, who said the property was good. Therefore he thought that the views of their late manager were wrong. He would remind them that in the early days of Nigeria the first men who went there said there was no payable tin in the place. He could mention dozens of mines which had been turned down in Nigeria which afterwards proved highly payable, so he thought that their late manager had made a mistake and the sooner they got another man there the better. If he might make a suggestion to the directors he would like them to select Mr. Wham, if he had the time to undertake the work. Then there was a reference made to the gold. In 1914 he went out there and saw two areas owned by the Champion Company, and he could not understand why those areas were not developed. There were places where free gold is found in the outcrop. The Champion Company took some 5,000 odd ounces of alluvial out of the river, which cut through the reef. In any other country they would have had a shaft sunk before this. However, there were great prospects for gold in Nigeria, but like other countries there would be good patches and bad patches.

Mr. R. B. Wham said that one of his main ideas in coming home was to try and push along the pipe-line, by means of which they could further prospect their Monguna leases, and also produce tin. They had a very good show out there, but it wanted further prospecting.

The resolution was seconded by Mr. St. John Winne, and unanimously carried.

INDO-BURMA OILFIELDS (1920), LTD.

Directors: Earl of Denbigh (*Chairman*), Lt.-Gen. Sir E. A. Altham, Gen. Sir Bindon Blood, H. G. Latilla, C. Perkins, R. F. M. Scott. *Secretary:* J. J. Sneddon. *Office:* Finsbury Pavement House, London, E.C. 2. *Formed* 1920. *Capital Issued:* £1,380,000.

Business: The development of oil lands in Burma.

The first annual general meeting of the Indo-Burma Oilfields (1920), Ltd., was held on December 1 at Winchester House, London, E.C. 2, the Earl of Denbigh (Chairman of the company) presiding.

The Chairman, in moving the adoption of the report and accounts to March 31, 1920, referred to the change made by the directors in the programme of the company from what was outlined in the prospectus issued when the company was formed. The prospectus declared the policy of the company to be the development of its Yenangyaung well sites. The Yenangyaung field was well known as an oil producer, and it was from that field that most of the oil in Burma had been derived. Orders were placed both in this country and America for the heavy machinery, tools, etc., for the work to be done on these sites. Like all other companies during the year 1920 this company had great difficulty in getting delivery of the machinery and plant ordered by it, and in the meantime the local staff were able to give more attention to the company's outside areas, particularly Yenanma and Padaukpin. As a result of a detailed examination of these areas they strongly urged the board to drill trial wells on them. Mr. Davies, the company's geologist, agreed with these recommendations while not in any way receding from the opinion he had expressed as to the value of the company's Yenangyaung well sites. Information was also received from reliable sources that the production from the Yenangyaung field, as proved by recent drilling, had shown a serious decline. After giving the matter the fullest and most anxious consideration, and believing it to be in the best interests of shareholders to get oil at the earliest possible date, the directors authorized work to be started at Yenanma. The first well drilled came in with a production of 6½ barrels per day at 690 ft., against the prospectus estimate of 3 barrels. Seventeen wells had been drilled in the neighbourhood of No. 1 well, and the results were set out in their technical adviser's report. Four further wells were being drilled, and the results might be received at any time. Oil had been struck in every well, the six best giving results of 12, 14, 18, 25, 30, and 45 barrels per day respectively. Results from three wells had been cabled since the report was issued; No. 20, which produced 11¼ barrels per day, No. 21 producing 18 barrels, and No. 22 producing 30 barrels.

In the Padaukpin area, work was commenced in No. 1 well in January, 1921, and in No. 2 well some little time later. It was subsequently discovered, as the result of a large-scale survey, that the centre of the dome was situated on an area of 1·8 square miles contiguous to the company's original area. This area was the property of a Burmese syndicate, from whom the company's managing agents obtained an option to purchase at the price of £17,500, and they had now turned the whole of this area over to the company at the price they paid for it, subject only to the same royalty as is payable in respect of the original area. Five sites were located on that area, and No. 3 well struck the oil at a depth of 1,414 ft., the yield being 63 barrels per day. No. 1 well was drilled to 1,950 ft., when on account of bad caving-in it was decided to abandon it. No. 2 well had now reached a depth of 782 ft., No. 4 well a depth of 1,450 ft., and might strike the oil at any time. No. 5 had reached 705 ft., and No. 6 100 ft. The rig was erected on No. 7 well. This was very satisfactory and the company was to be congratulated in owning a property of such great possibilities.

The satisfactory results from the Yenanma and Padaukpin areas fully confirmed and justified the change of programme in making the development of these areas the principal work of the company, but the directors had no intention of allowing their valuable well sites at Yenangyaung to lie dormant. As, however, the Yenanma and Padaukpin operations could be controlled easily and satisfactorily from a central base at Thayetmyo, the starting of work at Yenangyaung would have meant the duplication of staff, stores, machine shops, etc. The company had a short time before completed negotiations with the Yomah Oil Co., Ltd., for the erection of a joint refinery, and as the Yomah Company were drilling at Yenangyaung, an arrangement was made with them to drill a number of the company's sites on a co-operative basis.

As regards the refinery, on making careful search for a suitable site, it was found that the Yomah Oil Company had already acquired the best site which could be discovered anywhere in the neighbourhood of Rangoon. That company had already ordered a considerable amount of material, and eventually it was decided to join with them in the erection of a co-operative refinery. A separate company known as the United Refineries Burma, Ltd., was registered, two-thirds of the capital being found by their company, and one-third by the Yomah Oil Company, the profits to be divided in accordance with the amount of crude oil passed through the refinery by the respective companies. The first unit of this refinery was nearing completion

Further money had to be found, particularly for the company's share of the refinery, and an issue of £250,000 ten per cent First Mortgage Convertible Debenture Stock was made at the end of September last. This was all taken up.

He was assured that taking a moderate view the company could, beginning early in the New Year, count on earning profits of £10,000 per month, which sum would be progressively increased as production increased. With regard to the future programme, work would proceed with the present plant at Yenanma and Padaukpin continuously. The company's experts have the fullest confidence in the future of the company, and so had every member of the board.

Lt.-Gen. Sir E. A. Altham seconded the resolution, and it was carried unanimously.

PREMIER OIL CO., LTD.

[illegible] F. H. Hamilton (*Chairman*), J. Fairbairn, C. Perkins, H. Auerbach, H. G. Latilla, A. Whittaker, [illegible] *Secretary*: R. Stanley Williams. *Office*: 62, London Wall, London, E.C. 2. *Formed* 1919, as a reconstruction of the Premier Oil & Pipe Line Co., Ltd. *Capital issued*: £3,197,671 10s. in shares of 15s. each.

Business: Has large holding in a French company owning oil properties in Galicia and Czecho-Slovakia.

The first ordinary general meeting of the Premier Oil Company, Ltd., was held on December 9 at River Plate House, Finsbury Circus, London, E.C., Mr. F. H. Hamilton (Chairman of the company) presiding.

The Chairman, in moving the adoption of the report and accounts, said that when the present company was formed the Germans, or rather neutrals under German control, had physical possession of the properties in Galicia, largely through subsidiary companies or individual representatives who were entirely under their control. The old Premier Company, of which this company was the successor, was in debt to the extent of considerably over £100,000 before the war to the German groups. Subsequently this company succeeded in getting Polish sequesters appointed to carry on the business of the company. At an extraordinary general meeting of the company, held in June of last year, certain proposals for carrying through the sale to a French company were placed before shareholders, and were unanimously adopted, and the directors reported in a circular dated February 2 of this year that the arrangements, as authorized at the meeting in June, had been carried into effect, and that the French company had entered into possession of the properties early this year.

The reports upon the properties in Galicia, now published, were of very detailed character They included one report from Mr. Campbell Hunter, who was appointed as the company's representative to report independently of the French company, and another from Mr. H. Vilter, general manager of the French company. Altogether they carried things down to the beginning of October, and presented a clear and detailed picture of the position and of the progress that had been made during the first three-quarters of the year. Broadly speaking, the record was a highly satisfactory one, especially when it is borne in mind that it was only during this year that the French company assumed control. Production was increasing, an active drilling programme was being maintained, a large scheme of electrification, which would effect important economies, was making good progress, and for the months for which the French company had complete figures satisfactory profits were earned. The difficult task of reorganizing the very intricate machinery of the company had been tackled with energy and intelligence, and to-day they had a working organization absolutely second to none in Galicia.

A question of great importance—namely, the prolongation of leases—had been settled in a highly satisfactory manner. As the report showed, a certain number of the leases, the most important of which was that of the State Land Territory, had but a short time to run. In the case of the State Lands between five and six years remained—far too short a period to justify the expenditure of capital upon wells, although they were advised that the ground was rich. Owing to energetic representations made to the Polish Government, which were strongly supported by the representative of the French Government in Warsaw, the leases had now been extended for a further period of twenty years from the date of the expiration of the original lease, against a cash payment of 1,000,000 francs. Favourable arrangements had also been made with regard to the other leases, but the contract with the Polish Government regarding these State lands was of the greatest importance and should secure to the French company a large and increasing production from this source alone for many years to come. Of course, the extravagant and almost grotesque variations in the Polish exchange was a disadvantage, but this might easily be exaggerated.

As regards the relationships between the company and the French Premier Company, it might be well to point out with some precision what they actually were. They owned about 35% of the ordinary capital and about 40% of the parts de fondateurs, or, as they might be termed, the deferred capital of the company. The control of this, the English Premier Company, was, of course, vested absolutely in its shareholders. The control of the French company was secured to the French groups, not merely by the fact that they held a majority of the shares, but specifically under clauses in the agreement of sale. This company, however, had four directors upon the board of the French company, and the French company had two representatives, Messrs. Auerbach and Paix, upon this board. The relationships between the two companies were therefore of necessity very intimate, and during all the stress of the extremely difficult time through which they had been passing, and the complicated adjustments necessitated by the transfer of the properties and various contracts, the relationships had up to the present been of a frank and cordial character.

It was desirable at this meeting that they should consider very briefly the results of this transfer to the French company, with all its advantages and disadvantages in the light of the experiences of the last twelve months. The present board was responsible for it in a very special sense. They advocated the policy, found the buyers, and finally they conducted the very intricate negotiations, here and in Paris, over a period of some eight months. If the policy was a wrong one they had no one else than themselves to blame. They could best answer the question by asking what would have been the situation to-day if they had preserved the previous status. Obviously they would not have been in possession of the properties. They would still have been held by the sequesters representing the Polish Government, and they would have had not a shadow of right to control their policy. Government representatives, whether Polish or British, were not the ideal managers of any industrial enterprise, and in this case the sequesters laboured

under peculiar disadvantages. They could not find the capital to carry out the reorganization that was imperatively necessary, and they were, moreover, hampered by a rather dangerous political movement which had for its object the expropriation of the properties in the interests of Polish subjects. Had they preserved the old status they would have been deprived of the backing and influence of the French Government, which was by far the most important political factor in Poland to-day, and had been in one way and another of great service to the company, and they would not have obtained the extension of the concession on the State Lands. The only alternative way of terminating the régime of the sequesters, with all its risks, was by means of a litigation before the Arbitral Tribunal under the conditions provided for by the Treaty of Peace with Austria. There were a large number of cases still awaiting decision by that tribunal, and it seemed to them that it might well be years before their case was heard. At the best it would have been a terribly expensive process, and they would have been under the disadvantage of fighting not merely Germans, but powerful neutrals to whom the Germans had nominally at least sold and resold the control. Finally, they would at the best have been forced to repay the money which the old Premier Company owed, which would have necessitated a further reconstruction of this company, and, above all, there was only too good reason to fear that by the time they gained possession of the properties they would, in the absence of development and capital expenditure, have deteriorated enormously. Those were the factors which influenced the board in taking the line they did. It was not an easy line at the time they took it, because, apart from anything else, it necessitated negotiations in London, Paris, Berlin, Warsaw, and Switzerland, and the adjustment of a number of complicated interests; but, looking back after nearly twelve months, they had even less doubt than they had when they asked the shareholders' sanction for it that it was well worth the trouble, and that only by this means was this company saved from another and perhaps disastrous reconstruction.

The remaining question of practical importance related to their future policy. Certain shareholders had suggested to the board that as the Galician properties had been sold an immediate distribution of assets might be made. Even if that course were desirable, which in their view it was not, it was quite an impossible one at present, and, moreover, it would not be possible in any circumstances for two or three years. Under French law they, as vendors, did not receive negotiable documents of title, or, in other words, marketable shares, until two years after the registration of the company. In the meantime they were merely registered as entitled to receive certain shares in the French company. They would not be absolutely handed over to them until the end of next year. Moreover, they obviously could not distribute their 20,000 parts de fondateurs and ordinary shares of the denomination of 500 francs among their 12,000 shareholders. The only possibility was that they should sell them and distribute the proceeds over a certain term. As he had already said, that process could not be commenced for another year, and in dealing with so large an amount it would inevitably take a long time. Their own view was decisively against this policy of wholesale realization. For one thing they had high hopes of the future of the French company, and they considered that it had an excellent chance of developing into one of the most powerful and profitable combinations operating in Central Europe. It had valuable oil lands, extensive pipe-lines, a considerable portion of the refinery, strong resources, energetic management, and a strong financial and political backing. Even to talk of wholesale realizations at a period of acute depression such as they were now passing through and at a time, moreover, when the company was making rapid and substantial progress was a grave mistake. At the same time they were not blind to the advantage of some kind of capital distribution, and although nothing could be done in that direction at present, it did seem that if conditions were favourable a fairly substantial distribution might be possible, while still leaving this company with an important holding in the French company, and leaving it as an active organization apart from and outside the French company.

They had the bulk of their money on deposit at short notice, or on good security. The only important exception to this was that they had underwritten and purchased some £80,000 of 10% debentures in the Indo-Burma Oil Company. The exception was apparent rather than real, because the debentures were redeemable in three years at 110. They had no doubt either of the soundness of the security or of the wisdom of the transaction. Two of their directors—one of whom was Mr. Perkins, who was managing director of the company—were also directors of the Indo-Burma Company. They went carefully into the question of security, and they were convinced that the margin for an issue of £250,000 was ample, that the convertible rights carried by the debentures might easily become very valuable, and, of course, the return allowing for the underwriting commission and the price of redemption, was an exceptionally good one. Moreover, they had availed themselves of the opportunity of securing free of cost an option to acquire what were reported to be valuable oil-bearing areas in Burma. So far nothing had been done here, and no expense had been incurred, but they proposed almost immediately to send out the best independent experts they could secure and get their own reports upon these areas. They had reason to believe that the oil business in Burma was only in its infancy, and they had knowledge that certain important groups were actively engaged in exploitation schemes in that country. Burma had many advantages. Generally speaking, the oil was of the highest grade, was obtainable at shallow depths, and commanded a ready market. Moreover, Burma was under the British flag. The areas under offer had been taken up during the last four years, as a result of much effort, and under the best local advice available. Before embarking upon any programme of development they would send out their own experts and be guided by what they told them.

Mr. J. Fairbairn seconded the motion, and after the Chairman had answered questions from shareholders it was carried unanimously.

LUIPAARDS VLEI ESTATE AND GOLD MINING CO., LTD.

Directors: Sir Leigh Hoskyns (*Chairman*), W. Dereham, F. H. Hamilton, F. Turk. *Secretary*: W. Smith. *Office*: [illegible], 11, [illegible], London E.C. 2. *Formed* 1888, reconstructed 1896. *Capital issued*: £472,012; debentures outstanding £55,995.

Business: Operates a gold mine in the Western Rand.

The ordinary general meeting of the Luipaards Vlei Estate and Gold Mining Co., Ltd., was held on November 30 at Winchester House, London, E.C., Sir Leigh Hoskyns, Bart. (Chairman of the company), presiding.

The Chairman, in moving the adoption of the report and accounts for the year ended June 30 last, said that the improvement in the profit and loss account over the two previous years was considerable. There was a net profit of £22,960, compared with a loss during the previous year of £2,596, and a loss of £5,316 during the year before. This result was partly due to the effect of the price which was obtained for the gold, the average for the year having been £5 12s. 1·07d. It was further due to the fact that they had virtually suspended development from July 1, 1920, and it was further due to the retrenchment scheme, which, in agreement with the mine workers, was instituted in May of last year, and which had brought about a considerable reduction in the number of white men employed in the mine. The gradual reduction of working costs, both as to labour and stores, might be regarded as permanent, but development could not, of course, be suspended indefinitely, and, in fact, they had already, since July 1 last, resumed development, and were paying for it out of monthly revenue. The re-estimate made by the manager on June 30 last showed fully-developed pay ore in the mine amounting to 624,766 milling tons, of an average value of 5·20 dwt. per ton, and partially-developed ore amounting to 84,564 milling tons of pay ore, of an average value of 5·71 dwt. per ton. Although there had been crushed during the year nearly 207,000 tons, the ore reserves showed a reduction against the previous year of only 77,081 tons. The board were inclined to attach some importance to the acquisition which was made some nine months ago of twenty-two claims adjoining the property on the western side. Those claims would add some 260,000 tons of pay ore to the reserves not included in the above-mentioned figures, and adding those twenty-two claims to the ore reserves in other parts of the mine they had a total reserve representing nearly four years' crushing. It was the intention to give increased attention in the near future to the development of the Battery Reef sections of the property. This company, together with all the low-grade mines on the Rand, had been passing through several years of acute depression, but there was every reason to think that the clouds were passing.

Mr. W. Dereham seconded the motion, and the report and accounts were adopted.

WITBANK COLLIERY, LTD.

(*Incorporated in the Transvaal.*)

EXTRACTED FROM THE ANNUAL REPORT
for the Year ended August 31, 1921.

Issued Capital, £350,000 in 350,000 Shares of £1 each.

Directorate: Sir Harry Ross Skinner, Kt., M.Inst.C.E. (*Chairman*), Sir Evelyn Wallers, K.B.E., E. G. Izod, M.B.E. (*Managing Director*), Major C. S. Goldman, P. Dreyfus, Sir Abe Bailey, Bart., K.C.M.G., M.L.A., J. Jeppe, C.B.E., H. A. Rogers.

		£	s.	d.
Total profit for the year		155,952	9	3
Balance unappropriated at August 31, 1920		97,751	0	10
Making a total of		253,703	19	1
This amount has been dealt with as follows:—				
Expended on Capital Account less Sale of Township Stands and Freehold Property (£7,765 18s. 1d.)	£14,034 9 1			
Government Taxes	17,217 2 8	31,251	11	9
		£222,451	18	4
Dividends declared during the year:—No. 32 of 17½% and No. 33 of 15%		113,750	0	0
Leaving a balance unappropriated of		£108,701	18	4

During the year 1,117,680 tons, including 105,277 tons of duff, were despatched from the Colliery, being an increase of 122,091 tons as compared with the previous year.

The full Report and Accounts may be obtained from the London Secretaries, A. Moir & Co., 1, London Wall Buildings, London, E.C. 2.

NEW MODERFONTEIN GOLD MINING COMPANY, LIMITED.

Directors : Sir Evelyn Wallers (*Chairman*), J. R. Leisk, Sir H. Ross Skinner, J. G. Currey, C. S. Goldman, S. C. Black, R. W. Fennell, W. T. Graham. *Secretaries :* Rand Mines, Ltd. *Head Office :* Johannesburg. *London Office :* 1, London Wall Buildings, E.C. 2. *Formed* 1888. *Capital :* £1,400,000.

Business : Operates a gold mine in the Far East Rand.

The twenty-fourth ordinary general meeting of New Modderfontein Gold Mining Co., Ltd., was held in Johannesburg on November 4, Sir Evelyn Wallers, K.B.E., presiding.

The Chairman, in moving the adoption of the report and accounts for the year ended June 30 last, said that the position must have given shareholders the greatest satisfaction. The scale of operations and the total working profit derived from those operations were the greatest ever obtained by the company. They milled during the year 1,083,000 tons, yielding 9·741 dwt. per ton, representing an increase in tonnage milled of 114,500, and a decrease in grade of 0·58 dwt. per ton. The latter point was a desirable feature of the year's work, because, although the value of the ore mined was still somewhat above the average value of the ore reserves, it was decidedly below the average value of the tonnage developed during the year. The number of fine ounces recovered was 527,477, with a total extraction of just under 98%, which constituted extremely good metallurgical practice. The price obtained for the product was appreciably higher than for the previous year, namely, £5 12s. 7d. per fine ounce, as against £5 2s. 3d. for 1919-20. Obviously this factor had a very marked effect upon the profit. Working costs increased by 1s. 6d. per ton milled, but notwithstanding this fact, combined with the decrease in yield of 0·58 dwt. per ton, the final working profit showed an increase of 7d. per ton. The total profit for the year was £1,720,202 17s. 4d., of which £751,427 was obtained from the increased price of the product above standard price. The appropriation account showed that they commenced the year with a credit balance of £344,025 13s., and this amount added to the year's profit and including a small amount of £763 12s. 9d. in respect of forfeited dividends, gave for disposal a total of £2,064,992, 3s. 1d. The distribution had been as follows :—

	£	s.	d.
Dividends Nos. 29 and 30 .	1,400,000	0	0
Government and Provincial Taxes	297,950	9	5
Net Capital Expenditure after allowing for Bewaarplaatsen receipts . .	60,193	3	7
Balance unappropriated and carried forward . .	306,848	10	1
	£2,064,992	3	1

Development operations during the year were carried on with activity, and showed a substantial increase as compared with the preceding year. The total footage was 20,165, of which approximately 14,000 ft. developed ore, and the remaining 6,000 ft. was in the nature of dead work and the various purposes connected with the handling of the ore. The results achieved by this work in all directions were entirely satisfactory as to the values exposed. They had from time to time directed attention to the encouraging values which were likely to be met with in the western and south-western sections of the mine, and the work which they were able to do year by year confirmed in a very gratifying way the opinions expressed. Thus, on the 13th level west good values were disclosed after passing through a dyke and were referred to at the last annual meeting. These values had been energetically followed up during the year which he was reviewing, and resulted in the development in that locality of 302,800 tons of ore of a value of 9·7 dwt. over 82 inches. On the eastern side of the mine the result of the work carried out was equally satisfactory, and the final outcome of the year's development operations was that all ore mined was replaced, and, indeed, the ore reserves at 8,884,600 tons of a value of 8·4 dwt. showed some little increase in tonnage when compared with the previous year.

The total available area of the mine was 1,264 claims. Of these, 361 claims were worked out, but still contained a number of valuable pillars; 378 claims represented the intact developed area, and 525 claims still remained to be developed. In other words, about 28% of the property had been worked out, and 72% remained, which included, of course, the developed area representing 30%.

The health conditions of the mine were in first-class order, having been commented on by the District Inspector of Mines in very appreciative terms, and he could say with the utmost confidence that the general underground position was in most excellent shape. On the surface a similarly gratifying situation was met with. The increase to the eastern reduction plant, which brought their total capacity up to at least 105,000 tons per month, was completed during the year, at the very moderate cost of £14,000 and was now running well.

The other items of importance on capital expenditure were £22,000 expended in providing additional houses for married employees, and £16,700 for extension to their water system. In regard to this latter item they had had some anxiety in the dry season owing to the fact that the number of consumers, of whom they were one, drawing water from the President Dam had appreciably increased. They therefore considered it prudent to spend this money on making the position secure, by connecting up their storage reservoirs with the Rosherville Dam. For the current year no capital expenditure of any particular importance was contemplated.

In order to bring the information up to date, he would briefly review the salient features of the work since the close of their financial year, that was during the last four months. The native labour force had continued to hold up well, and their tonnage milled had steadily progressed. In July the figure was 96,000; August, 100,000; September, 101,000; and in October they reached a total of 107,000. Working profits had been respectively £141,800, £153,100, £142,900, and £138,000. There was naturally some decrease in profit, due to the

[illegible] realised for the price of gold, but the [illegible] the reduction in the price of their product had been counteracted in a very satisfactory way by the increase in the tonnage milled. Working costs over the last four months had shown an encouraging decrease; the figures for the respective months per ton milled were 22s. 9d., 22s. 4d., 22s 2d., and 21s. [illegible], compared with the average for last year of 23s. 5·5d. The development work since July last had also been very energetically pushed, and they had averaged well over 2,200 ft. per month. The values exposed on the whole had been of high grade, both east and west. There were four winzes not yet very far advanced going down from the 14th level and constituting their present lowest workings, two on the west side of the circular shaft and two on the east side; three of those winzes were exposing ore of an average value of approximately 1,000 inch-dwt. At the present footage rate practically the whole of the mine above the 14th level would be completely developed in about two years' time, and the scheme for the development of the mine below the 14th level to the southern boundary was already receiving attention, although there was ample time in which to formulate their plans. In any case the problem was one of comparative simplicity. Considerable attention was being given to the cleaning up of the old workings, and to facilitate this work a sand-filling scheme of some magnitude was now being put in hand on the upper levels on the east of the mine; at the same time opportunity would be taken to further prospect a few isolated blocks of ground which had been left standing in the past as of doubtful payability.

At the last annual meeting reference was made to the question of the enemy shares vested in the Custodian of Enemy Property. The company made an offer for those shares, which was not accepted. They, therefore, still remained in the hands of the Custodian, but shareholders might rest assured that the directors were carefully watching the situation, and if there was any possibility of acting in their interests on a satisfactory basis, the opportunity would not be lost.

All that he had said indicated again in an unmistakeable manner not only the extraordinary soundness and strength of position of the mine, but also the excellence of the year's work of the general manager, Mr. Miles Sharp; the underground manager, Mr. Tillard, and the staff and employees generally. Mr. Stuart Martin continued to act as the consulting engineer with conspicuous success. Shareholders would, he was sure, join with him in recording their very keen appreciation of their services.

Mr. S. C. Black seconded the motion, and it was carried unanimously.

NOURSE MINES, LIMITED.

Directors: E. G. Izod (*Chairman*), W. T. Graham, H. Nourse, A. L. Mallins, W. Dereham, G. S. Hutt, Sir Evelyn Wallers, S. C. Black, L. J. Renaud, E. Raleigh. *Secretaries:* Rand Mines, Ltd. *Head Office:* Johannesburg. *Formed* 1894. *Capital issued:* £827,821.

Business: Works a gold mine in the central Rand.

The twenty-fifth ordinary general meeting of Nourse Mines, Ltd., was held in Johannesburg, on November 4, Mr. E. G. Izod, M.B.E., presiding.

The Chairman, in moving the adoption of the report and accounts for the year to June 30, said that the profit earned was £118,347, a substantial increase of £30,377 over the figure for the preceding year. In spite of a slight fall of 0·146 dwt. in the yield, working revenue increased from 33s. 1d. to 35s. 6s. per ton milled, due entirely to the higher price obtained for the gold. Working costs increased by 1s. 5d. per ton milled, due very largely to the increased cost of stores, the amount spent under this heading being £49,845 in excess of that spent for the previous year. In his last speech he referred to the attention which was being given to the water position. On a mine like the Nourse, with what was virtually an abandoned outcrop mine above it, the problem of dealing with water was always a serious one. With the completion of the centrifugal pumping unit they were able to deal with all their present water and have a substantial margin in hand for emergencies. Realizing, however, that further precautions might be taken to minimize the water danger, they investigated the surface of the New Heriot, which mine ceased pumping operations more than twelve months ago. They decided that if they could obtain control of the water-right on the New Heriot, together with certain surface claims, which were for disposal, they could probably prevent a large amount of surface water from entering their workings, and they accordingly purchased for £5,500 the claims and water-right mentioned. By suitable attention to the surface of the ground so acquired, they had been able substantially to reduce the water handled by their pumping plant, and the saving in pumping costs had already been more than the expenditure on the acquisition of the claims and water-rights.

The profits earned for July, August, September, and October of this year totalled £34,274. Working costs at an average of 31s. 9d. per ton milled were higher than the average for the financial year covered by the report and accounts, and it was only the maintenance of the high price obtained for the gold that had enabled them to make profits. Work on the programme in connexion with No. 1 shaft South Nourse was proceeding satisfactorily. This shaft reached the horizon of the 27th level in July, and the 27th level cross-cut had already advanced approximately 130 ft. out of a total of about 800 ft. necessary to strike the reef. The 25th level cross-cut from this shaft had advanced 80 ft. and was expected to strike the reef at about 350 ft. from the shaft. The new large Ward-Leonard winder on the surface at this shaft had been working satisfactorily. Development continued to be promising. On the western side of the mine, in the No. 2 South Nourse section, the Main Reef Leader disclosures were good.

Mr S. C. Black seconded the motion, and it was carried unanimously.

CHINESE ENGINEERING AND MINING CO., LTD.

Directors: W. F. Turner (*Chairman*), F. Cattier, Edmund Davis, E. de Wouters, E. Francqui, L. Jadot, Col. H. A. Micklem, Lord Southborough. *Agent and General Manager in China:* Major Walter Nathan. *Secretary:* A. W. Berry. *Office:* 22, Austin Friars, London, E.C. 2. *Formed* 1912. *Capital issued:* £1,400,000; debentures £1,008,000

Business: Operates coal mines in North China; is also interested in iron deposits.

The ninth annual ordinary general meeting of the Chinese Engineering and Mining Co., Ltd., was held on Monday, December 12, at Winchester House, London, E.C., Mr. W. F. Turner (Chairman of the company) presiding.

The Secretary (Mr. Alfred W. Berry) having read the notice convening the meeting and the auditors' report,

The Chairman said: The distinguishing feature of the report and accounts for the year ended on June 30 last, which we submit to you to-day, is that, while owing mainly to the fall in the average rate of exchange, they deal with smaller figures than those of the preceding year, the net result is equally satisfactory. For the year ended June 30, 1920, we paid a dividend of 30%, free of income tax, on a share capital of £1,000,000. The balance dividend of 12% which we propose to declare to-day will make, with the interim dividend of 10% paid in May last, a total of 22%, free of income tax, on the increased capital of £1,400,000, so that we shall be distributing £308,000 in dividends, against £300,000 in the preceding year. It must be borne in mind that the 400,000 new shares did not constitute any addition to the working capital of the company. It was merely the capitalization of profits which had accumulated during past years.

The net profit of the Kailan Mining Administration, after providing for interest on the 6% Kailan bonds, redemption of bonds for the year, reserve for depreciation, and the profit to which the Chihli Government is entitled, was $7,313,448, against a net profit of $8,917,456 for the preceding year. This result, as you will have seen from a later paragraph in the report, is due, not to any falling off in the demand for coal, but solely to difficulties in regard to railway transport, and it compares very favourably with the profit of about $6,000,000 two years ago.

Our share of the profit amounts to $3,850,012. We were careful to point out to you at the meeting last year that the profits of that year had been largely increased by the high rate of exchange which had prevailed throughout the year. The average rate for the past year shows a reduction of about 2s. per dollar, and the amount brought to credit of our profit and loss account therefore works out, including interest in China, at £564,723. Interest in Europe is £72,221, and there are some small items which bring up the total to £641,469.

Expenses in Europe are larger than before, as I told you they would be. There is a donation of £5,000 to the China Famine Relief Fund, which was reported at the last meeting; exchange amounts to £16,259, and there is a loss of £11,942 on the sale of 5% War Loan. Two of these items, amounting to nearly £17,000 will not recur. The net balance of profit on the year is £587,994.

You will find a statement in the accounts showing the disposal of the profit balance at June 30, 1920, the chief items being the final dividend, which was £200,000, paid on December 17, 1920, and the £400,000 which was applied in making fully paid the 400,000 shares of £1 each allotted on May 12 last, pursuant to the resolutions of the extraordinary general meeting held on January 4, 1921; the £37,784 remaining is brought into the following year. We have, therefore, a total credit to profit and loss of £625,779. Income tax absorbs £112,316, excess profits duty requires £122,304 to bring up the reserve to the required figure of £189,000, and corporation profits tax is £26,600. These three items, making a total of £261,220, form our contribution to the Inland Revenue, and, as you see, they amount to almost exactly 45% of the year's profit. The interim dividend of 10%, free of income tax, paid on May 23 last, was £140,000, so that we have a balance of £224,559 to deal with to-day.

I have already said that we propose to declare a balance dividend of 12%, free of tax, payable to-morrow, the 13th instant. The further remuneration to which the directors are entitled under the Articles of Association is £9,133, and we propose to write off the whole of the expenses in connexion with the increase of capital (consisting chiefly of stamp duties), amounting to £25,685, so that there will be a balance of £21,740 to be carried forward to the current year. This result is more gratifying when one bears in mind that the profits have had to bear a charge of £122,000 for excess profits duty, and that the company's liability to that impost ends with these accounts. The company will have paid in all for excess profits duty over £1,400,000.

As regards the balance sheet, there are only one or two items to which I need refer. The first is the increase of the share capital from £1,000,000 to £1,400,000. On the other side of the account you will see that our loan account to the Kailan Mining Administration has been increased from £50,000 to £152,000, a sum of £102,000 having been provided by us and a similar amount by the Lanchow Mining Company for further working capital of the Kailan Mining Administration. It is quite likely that we may very shortly have to contribute another £100,000 of working capital.

The next paragraph of the report relates to excess profits duty and the directors' remuneration. There is a provision in the Finance Act of 1916 to the effect that a company may recover from the directors the amount of excess profits duty payable by the company in respect of any increased remuneration above a certain limit. The object of the section was to prevent salaries or remuneration of employees or directors being increased capriciously for the purpose of reducing a company's liability to excess profits duty. No consideration of that sort arises here. The effect of the section in our case would be to defeat, to a certain extent, the object of the resolutions passed by the shareholders last year, and it would operate inequitably as between the individual directors who are concerned. The amount involved is about

[illegible]. It is [illegible] proposed that the section [illegible] not be acted upon.

The next paragraph deals with the business done by the Kailan Mining Administration during the year. The sales of coal amounted to 3,775,000 tons, a [illegible] of 235,000 tons compared with the preceding year. This is not due to any falling off in demand for coal. It is entirely a question of railway transport.

Major Nathan reports as follows: "The reduction recorded in sales is due to the following reasons: The internal troubles which occurred in the latter part of the last financial year and the beginning of this affected the transportation of coal for nearly six months, military interference on the railway and movements of troops decreasing the number of cars available for the coal traffic. No sooner were the troubles due to these causes overcome than the famine in Central China was again responsible for a reduction in our coal traffic, owing to the demands made on the railway for the export of grain from Manchuria for the relief of famine sufferers. These two reasons alone were sufficient to cause the reduction in sales which has been experienced during the year. The actual carrying capacity of the railway has not been greatly increased, the supply of trucks and locomotives having been practically stationary during that period. At the present time conditions are still unsatisfactory, although there is an improvement on our experience in the early part of the financial year under review. Towards the end of the financial year a great improvement was noticeable, largely due to the use by the Peking-Mukden railway of cars belonging to the Peking-Hankow line, and for a short period we were able to move by rail an average of about 15,000 tons per day. As a result of a traffic conference between the various lines the supply of these cars has been much reduced and the average at the present moment may be said to be about 12,000 tons per day, including a traffic of about 1,000 to 1,500 tons per day carried by our own cars to Hsukochwang and Hanku, from whence the coal is shipped by boat to Tientsin. We were enabled to increase our traffic in this way by a purchase of 200 small cars from the railway which they had thrown out of use. The burden of my monthly reports, as will have been noticed, has practically always been the same, namely, the want of cars and consequent inability to keep pace with the demand. It has been my great endeavour to persuade the railway to double the track between the mines and Chinwangtao and to purchase sufficient rolling stock to meet our demands for transport facilities, and I am pleased to say that I have at last been successful in inducing the authorities to carry out the doubling of the track and also the supply of further locomotives and cars. The effect of the latter will be seen, I hope, towards the end of the present calendar year, but that of the former, I anticipate, not before the end of 1922 at earliest."

Now as regards the prospects of the current year, Major Nathan writes: "Sales of coal have been limited only to our transport facilities, and therefore no comparison can be made with former years as to the possibility of increase if facilities had been available for the transport of our coal by rail to Chinwangtao to meet the demand. It can only be said that we were obliged to neglect or entirely abandon any attempts to develop our overseas market. The same condition will apply to a certain extent during the present year, but the quieter conditions now prevailing in the country will undoubtedly have the effect of allowing of a considerable increase in our sales compared with last year. At the time of writing, in the first three months of the financial year 1921-22, our sales have augmented by a quarter of a million tons as compared with the same period in 1920-21. Although these figures are not likely to be maintained throughout the whole year, there is no reason to expect that our sales will not be considerably higher than in the year under review."

The stock of coal at the latest date we have was about 370,000 tons. Our output capacity is 15,000 tons daily, and Major Nathan states that, given fair labour conditions, he has every expectation of reaching a total production of over four and a half million tons during the current financial year. The coal in sight at June 30 last is given as 24,435,000 tons. The yards at the port of Chinwangtao have been extended to allow the handling of 15,000 tons of coal per day and the storing of 260,000 tons. The sales of coal during the first twenty-three weeks of the current year amount to 1,841,000 tons, as compared with 1,521,000 tons for the same period last year, an increase in round figures of 320,000 tons. The average rate of exchange for the present financial year, so far as it has gone, is approximately 2s. 9d. per dollar, and does not differ materially from that of the preceding year. The business prospects, therefore, are entirely satisfactory.

At the last general meeting we explained at some length the position of matters in regard to the project for the establishment of iron works at Chinwangtao. The matter has been followed up throughout the past year and considerable progress has been made. Mr. David Roberts, of Cardiff, who is a well-known blast-furnace engineer, went out to China on behalf of Messrs. Riley & Harbord, to inspect and decide upon the best available site for the proposed works. A satisfactory site has been chosen, and the necessary arrangements in regard to it are in progress. Further investigations are proceeding, especially in regard to certain deposits of iron ore and the treatment of them. These may still take a considerable time, and until they are completed a definite scheme cannot be formulated and adopted. In the meantime the prices of labour and materials are falling, and it is expected that there will be a saving of several hundred thousand pounds in the ultimate outlay for plant, compared with the figures which we had before us a year ago. I now move: "That the directors' report and accounts to June 30, 1921, be, and they are hereby, received and adopted, and that a final dividend be declared of 12%, free of income tax, making 22% for the year, free of income tax, payable on December 13, 1921."

Colonel H. A. Micklem, C.B., C.M.G., D.S.O., formally seconded the resolution, which was then put to the meeting and carried unanimously.

The retiring directors (Mr. Félicien Cattier, Colonel H. A. Micklem, and Mr. W. F. Turner) having been re-elected, and the auditors (Messrs. Annan, Dexter & Co.) reappointed, the proceedings terminated.

SOUTH WEST AFRICA CO., LTD.

Directors: Edmund Davis (*Chairman*), Sir Henry Birchenough, F. Eckstein, D. O. Malcolm, H. P. Rudd, Admiral Sir E. J. W. Slade. *Secretary:* C. Launspach. *Office:* 1, London Wall Buildings, London, E.C. 2. *Formed* 1892. *Capital:* £2,000,000 ; issued £1,750,000.

Business: Owns land, mining, and railway rights in Damaraland, South West Africa.

The annual general meeting of the shareholders in the South-West Africa Company, Ltd., was held on December 6, at Winchester House, London, E.C., Mr. Edmund Davis (Chairman of the company) presiding.

The Chairman, in moving the adoption of the report, said that their original claim in respect of amounts held on deposit in Berlin, and sums which accrued to the company during the war period, had been dealt with at various dates. Their concession was a direct grant from the German Government, and covered such extensive rights that at a later date the company agreed to some modifications, and, in exchange for the rights they waived, were granted joint interest with the German Government in the mineral rights of Ovamboland, a territory covering about 20,000 square miles. It was, therefore, impossible to understand how the Union Government of South Africa, which held a mandate over South-West Africa, could justify their action in confiscating the mineral rights covered by the company's concessions. As shareholders were aware, the Government had cancelled the whole of the company's rights with the exception of its title to about 1,600,000 acres of freehold land and a certain exclusive right in regard to mineral areas. The accounts presented on that occasion were up to December 31, 1920, but, of course, they in no way reflected the position as at to-day's date. In those circumstances the directors desired to set out what would probably be the position as soon as effect had been given to the transaction relating to payments under their claim and to the purchase of shares by the company. In the first instance they might take it for granted that at any rate 1,200,000 of their shares would be acquired by the company, though the actual number might be slightly in excess of that figure. Those shares had been acquired from the Public Trustee at 11s. 6d. per share, with a formal approval of the Board of Trade, which was subject to passing the necessary resolution adopting new articles of association. Taking the figure 1,200,000 shares as being correct, those would be added to the unissued capital, thus reducing the issued capital to £560,000 in shares of £1 each. Against that capital they would have their British, Colonial, and foreign—other than German and Hungarian—investments, which at to-day's market price were worth about £516,000. To that should be added other items bringing the total to £673,027. Of course, due consideration would be given when framing their next accounts to the land sales account, which was really a reserve account, and stood at £84,503, and their balance of profit £95,238.

Mr. F. Eckstein seconded the resolution, which was carried.
